The guanosine of the G•U wobble base pair is recognized by the J4/5 region of the P4–P6 domain. The J4–5 region contains tandem A•A non-Watson–Crick base pairs that interact with the exocyclic amine and the 2'-OH of the guanosine in the wobble pair (Figures 3(a) and 3(b)). With the ribozyme 'pinched' down upon the guanosine in the wobble pair, the phosphate that follows the uridine is placed in an optimal position to interact with the guanosine nucleophile and the intron's active site. The requirement for a G•U instead of a G–C Watson–Crick base pair at this position can be attributed to two characteristics of this special base pair. First, the exocyclic amine of the guanosine is displaced into the minor groove, allowing it to hydrogen bond to the J4/5 region. The exocyclic amine of a guanosine within a G–C base pair is involved in hydrogen bonding to the cytosine and is, therefore, sterically occluded from this interaction. Second, if the guanosine base in a G•U base pair is superposed on the guanosine G–C base pair, the position of the pyrimidine (U or C), and, therefore, the phosphate at the 3' position, is quite different in the two structures. Displacement of the uridine toward the major groove as occurs in a wobble base pair is required to place the phosphate at the 5' splice site into the active site of the intron.

In summary, group I introns may be thought of as RNA restriction endonucleases, capable of recognizing double-

stranded RNA and specific for cleavage at G•U wobble base pairs. The catalytic activity of group I introns is dependent on proper folding of the RNA into a stable three-dimensional structure containing three domains. The three domains act cooperatively to position the 3'-OH of the guanosine nucleophile, the 5' splice-site phosphate, and at least two magnesium ions bound in the heart of the ribozyme (Figure 4), and thereby promote catalysis.

Glossary

Cyclin-dependent kinase (CDK) A family of kinases that requires binding to a regulatory subunit called a cyclin to be active against exogenous substrates.

DDK DBF4-dependent kinase Cdc7, required for replication initiation.

Go-Ichi-Ni-San (GINS) Initiation complex, named for the Japanese Go-Ichi-Ni-San, or 5-1-2-3 after the names of the genes.

Origin Site of replication initiation in the genome; usually intergenic, but often has no defining sequence.

preRC Pre-replication complex assembled before origin firing comprises ORC, Cdc6, Cdt1, and MCM proteins.

The process of DNA synthesis during S phase requires regulation at multiple levels to ensure that DNA replication is coordinated with overall cell-cycle progression. There are numerous mechanisms to ensure that S phase occurs in a timely and regulated fashion. These ensure that the onset of replication occurs in response to the appropriate signals, and they also prevent the re-replication of the genome in a single cell cycle. Much of this regulation occurs by controlling the activation of DNA synthesis at individual origins of replication.

The study of S phase and its many levels of control is continuing in many laboratories. This work has benefited from genetic systems such as the yeasts *Saccharomyces cerevisiae* and *Saccharomyces pombe*, and the fruit fly *Drosophila*. Biochemical studies, primarily in *Xenopus* extracts, complement early work that reconstituted the replication apparatus using viral systems and human cells. Given this long and distinguished history, there are inevitably different names for the conserved proteins involved. Table 1 provides a listing of the equivalents that are most relevant to this article.

Initiation and Elongation of DNA Replication Origins

The major control of DNA replication occurs at initiation, by regulating assembly and activation at the replication origins of the multiple proteins of the pre-replication complex (preRC). Following initiation, the enzymes of the DNA synthesis machinery take over and extend replication forks to duplicate the genome.

Origins

DNA synthesis begins at replication origins. Generally, there are many replication origins in each chromosome, to facilitate the timely duplication of the genome. In a few species, the origin is defined by a consensus sequence in the DNA. More commonly, origins are defined by general features of the sequence rather than a linear consensus, and are typically A/T rich and easily unwound. In some cases, origins appear to be distributed not by sequence, but by a spacing mechanism. Not all origins are activated at the same time: some regions of

the genome may undergo initiation early in S phase, others are activated late. Moreover, not all origins are used in every cell cycle, leading to a stochastic distribution of origin activity. Some of this may reflect differences in chromatin structure and access, possibly depending on histone acetylation. Despite these differences in origin function, the proteins responsible for replication initiation at individual origins are remarkably similar among eukaryotes, and many of these factors can also be found in the Archaea.

Assembly of the preRC

The preRC is assembled by sequential binding of conserved proteins (Figure 1). This occurs at the end of M phase in cycling cells. First, the six proteins of the origin recognition complex (ORC) bind DNA near what will become the initiation site in the replication origin. Next, Cdc6 (called Cdc18 in fission yeast) and Cdt1 bind. These two proteins are highly regulated so that they are only available for this function at the beginning of S phase. It is likely that Cdc6 acts as a clamp loader to assemble the six-membered ring of proteins called the 'mini-chromosome maintenance (MCM)' complex (Mcm2–7). Biochemical studies suggest that once the MCM complex is loaded, the other preRC components are no longer required for replication initiation. Curiously, MCMs are extremely abundant proteins, far outnumbering the replication origins, and it remains to be determined why the cell requires so many of them (the MCM paradox). One model suggests that the spreading of MCMs across the unreplicated chromatin serves to distribute sites of replication, but this remains unproven. The assembled preRC is now poised for initiation of the origin. It is likely that more origins are assembled than will be needed, probably as a backup mechanism in the case of DNA damage or replication fork defects.

Initiation

Initiation at each origin occurs when several activating proteins are recruited sequentially to the assembled preRC in response to specific kinase activity (see section Regulation of Origin Firing by Kinases). Although the details may differ slightly from system to system, there are broad similarities. In all

Table 1 Proteins required for S-phase initiation

<i>S. cerevisiae</i>	<i>S. pombe</i>	Metazoans	Product

^bsequence homolog not (yet) identified.

cases, the Cdc45 protein is recruited, probably by a loading factor sensitive to Cdc7 and cyclin-dependent kinase (CDK) kinase. Subsequently, a complex including the BRCA1 C-terminal (BRCT)-domain protein Dpb11/Rad4/TopBP1 is recruited and helps load DNA polymerase epsilon and the go-ichi-ni-san (GIN5) proteins. The loading factors and Dpb11/Rad4/TopBP1 then leave the complex, but Cdc45 and GINs activate and travel with the MCM helicase. This creates a core unwinding complex called variously the 'replication progression complex (RPC)' or 'Cdc45-MCM-GIN5 (CMG)'. This recruitment allows initial unwinding of the DNA and binding by the single-stranded-DNA-binding protein replication protein A (RPA). This is the essential first step that leads to the full replisome.

Although Cdc45 and Dpb11/Rad4/TopBP1 are conserved, the other loading factors are not. The yeasts use proteins called Sld2 and Sld3. Vertebrate cells appear to undergo a similar regulation, but the likely candidates are not strongly related to the yeast proteins (RecQ4 and treslin).

Elongation

Elongation occurs as the cell couples DNA polymerases to the unwinding apparatus. The initial DNA synthesis relies on DNA polymerase alpha and an RNA primase. As the leading strand is elongated, a polymerase switch occurs, and the highly processive DNA polymerase epsilon assumes the job of DNA

synthesis. It is locked into place by a clamp called proliferating cell nuclear antigen (PCNA), which is loaded onto the DNA by a clamp-loader called replication factor C (RFC). Replication proceeds bidirectionally from the origin, with each leading strand generating a replication fork structure. While DNA polymerase epsilon elongates the leading strand, the opposite lagging strand is synthesized in a series of short fragments. These are initiated by DNA polymerase alpha and extended by DNA polymerase delta. These Okazaki fragments are joined together by a group of processing enzymes including DNA ligase, to create a single continuous strand.

In order to maintain the attachment between the DNA polymerases and the unwinding activity of the helicase, several additional proteins are recruited to the replisome as linkers. These proteins, AND-1/Ctf4 and Claspin/Mrc1, contribute to the stability of the replication fork and prevent the helicase from unwinding too far ahead of the polymerases. Loss of these proteins makes the cells more sensitive to DNA-damaging agents that result in replication fork stalling or pausing.

Processive DNA replication may be interrupted if the polymerase encounters lesions in the template, or if it runs out of nucleotide precursors. Checkpoint response mechanisms and DNA repair factors can be recruited to repair the defect and allow replication to continue. These are discussed in other articles.

Little is known about the resolution of two colliding replication forks from adjacent origins, or the termination of

Figure 1 Ordered assembly of the budding yeast pre-replication complex (pre-RC) is a model for eukaryotes and occurs during late M and G1 phase. Initiation at individual replication origins occurs during S phase when the MCM helicase is activated. Phosphorylation is indicated by stars and results in recruitment of DNA synthesis factors. Loading factors Sld2 and 3 and Dpb11 assemble the helicase processivity factors Cdc45 and GINS. Elongation occurs with the recruitment of polymerases: leading strand (pol ϵ), lagging strand (pol δ), and primase (pol α), and coupling factors Ctf4 and Mrc1.

replication. However, studies show that the MCM proteins are dislodged from the chromatin as S phase progresses, and by the conclusion of DNA synthesis they are no longer DNA associated.

Regulation of Origin Firing by Kinases

Activation of DNA synthesis at the assembled preRC requires the activity of at least two kinases: a CDK and a related kinase called Cdc7 (DDK). Investigators are still examining the molecular effect of these kinases, but a general model for their function has been determined (Figure 2).

Cdc7 (DDK)

The Cdc7 kinase is essential for initiation of DNA replication. It acts at individual replication origins to initiate DNA synthesis and, thus, is rate limiting for initiation. Its activity requires

binding to a regulated subunit, originally identified as Dbf4, which is required for the catalytic Cdc7 subunit to recognize its substrates and target it to the preRC. Dbf4 is regulated both transcriptionally and posttranslationally and restricts kinase activity to the S phase of the cell cycle. The Cdc7 kinase is sometimes called a DDK, or Dbf4-dependent kinase, in recognition of its similarity to cyclin-dependent kinases. *In vitro* data indicate that Cdc7 kinase can phosphorylate components of the preRC and initiation proteins, including MCM proteins, Cdc45, and DNA polymerase alpha.

A change-of-function mutation in *S. cerevisiae* MCM5 was isolated that completely bypasses the requirement for Cdc7 kinase. This led to the suggestion that phosphorylation of the MCM complex by Cdc7 results in a conformational change in the complex required for activation. Recent studies in budding yeast suggest that Cdc7 phosphorylation of the N-terminus of Mcm4 is required for MCM activation, although this has not been demonstrated for other systems. However, together the data suggest that Cdc7 activity is required for assembly of Cdc45. As described above, Cdc45 binding is a prerequisite for assembly of RPA and primase, and is thought to be limiting for replication. Thus, Cdc7 can be thought of as activating the proteins at the individual origins.

Cdc7 also has a variety of other substrates in S phase. It is required for proper timing of centromere DNA replication, centromere cohesion, and response to DNA-damaging agents. It also functions in meiosis to regulate programmed recombination and cohesin. These different activities can be mapped onto different domains of the Dfp1 protein.

Cyclin-Dependent Kinases

CDKs are the engine of the cell cycle and their oscillation controls multiple events. In yeasts, a single kinase subunit switches cyclin partners during the cell cycle to provide substrate specificity. In metazoans, multiple kinases combine with multiple cyclins to achieve the same specificity. Studies *in vitro* and *in vivo* investigating replication proteins show that CDK phosphorylates ORC, MCMs, RPA, and DNA polymerase alpha, as well as the specific loading factors required to assemble Cdc45 and GINS. CDKs play both positive and negative roles in the regulation of DNA replication: although initiation clearly requires CDK activity, the kinase is also required to prevent re-initiation of origins within the same cell cycle (Figure 2).

Data from several systems suggest that the positive role of CDK in replication initiation operates in a pathway parallel to Cdc7 activity. In the two yeasts, the conserved Dpb11/Rad4/TopBP1 protein interacts with Drc1/Sld3, which is a known CDK substrate. If Drc1 is not phosphorylated, it cannot bind to Dpb11. Data from *Xenopus* suggest that the Xmus101 protein (related to Dpb11) is required for Cdc45 binding. Together, these studies suggest that two components are required for Cdc45 and GINS binding: Cdc7 activation of the preRC and CDK activation of the Dpb11 pathway. This model is speculative. However, it provides an attractive fail-safe mechanism for the cell to ensure that multiple signals are integrated before it fires a single replication origin, which would significantly reduce the chance of aberrant initiation.

Figure 2 Positive and negative regulation of S-phase initiation prevents re-replication. The preRC is assembled on origins when CDK activity is low, and re-assembly is prevented when CDK activity is high. Origins only fire when both CDK and DDK are active on preRCs. Fluctuation in the levels or activity of cyclins, cyclin-kinase inhibitors (CKI), Dbf4 protein, and geminin contribute to this regulation. Under conditions when defects in replication block synthesis, Rad53 checkpoint kinase is activated to prevent further origin firing and to protect the structure of active replication forks. Gray text/arrows indicates inactivated pathway components.

Coupling Replication to the Cell-Cycle Engine

Activation and inhibition of replication from individual origins is controlled at multiple levels that ultimately depend upon the oscillation of CDK activity during the cell cycle. This oscillation reflects the control of the individual cyclins. The DDK subunit Dbf4 is also subject to this regulation (Figure 2).

CDK Inhibitors and Proteolysis

CDK activity is regulated at multiple levels, including phosphorylation. Most obviously, association of the kinase with transiently produced cyclin proteins provides temporal specificity (Figure 2). The cyclins are targeted for destruction by specific ubiquitination complexes at various points in the cell cycle. The Dbf4 subunit of the DDK in yeasts (and probably in larger cells) also oscillates in the cell cycle. It is regulated transcriptionally, and is also a target for ubiquitination during M phase, which restricts its activity to the S phase of the cell cycle. Thus, destruction of proteins in M phase helps maintain the timing of events in S phase.

Specific inhibitor molecules expressed during G1 also modulate CDK activity prior to S phase. These are usually specific to particular cyclin forms of the CDK. These inhibitors keep kinase activity repressed, which allows assembly of a preRC. As cells proceed toward S phase, the increasing levels of cyclin lead to increasing CDK activity which ultimately overcomes the inhibitor. The accumulating CDK phosphorylates its inhibitor, leading to its ubiquitination by an S-phase-specific complex that targets the inhibitor for destruction. Although this same general pattern describes most cell types, surprisingly the individual CDK inhibitor molecules in different species such as *S. cerevisiae* Sic1, *S. pombe* Rum1, and human p27^{Kip1} are highly diverged and show no primary sequence homology.

In mammals, cyclin D/CDK4 phosphorylates and inactivates the Rb protein. Active Rb inhibits E2F, a component of the S-phase-inducing transcription factor; thus, Rb needs to be inactivated before S phase can initiate. Because Rb inhibits entry into S phase and the cell cycle, its loss can lead to dysregulation of cell-cycle progression, so it is not surprising that Rb was originally identified as a tumor suppressor.

Activation of the preRC: Once and Only Once

The negative role of CDKs in preventing re-initiation of DNA replication is dramatically illustrated in fission yeast, in which overproduction of the CDK inhibitor Rum1 results in cells repeating S phase many times, without an intervening mitosis. The CDK is inhibited so it cannot promote mitosis, or prevent re-initiation of replication origins; however, the S-phase-promoting form of the CDK remains active.

The targets of the CDK for this inhibitory activity include several factors at the replication origin. Data suggest that the ORC complex is a CDK target that prevents re-replication. Similarly, Cdc6 protein is tightly regulated so that it is only present in the nucleus at the time of preRC assembly (between mitosis and S phase). It is a CDK substrate, and depending on the system, is either degraded or exported from the nucleus, in response to phosphorylation. In metazoans, Cdt1 associates with an inhibitor molecule called geminin, which itself is degraded during mitosis to free active Cdt1. Thus, active forms of Cdc6 and Cdt1 are only present at the time of preRC assembly to allow MCM loading. This provides one way to ensure that origins cannot be re-activated in a single cell cycle.

The MCM complex, although present throughout the cell cycle, can only bind at the origin in the presence of Cdc6 and Cdt1. The MCM complex is dislodged during replication, and some subunits are phosphorylated by CDK. In the yeast *S. cerevisiae*, this phosphorylation results in the active export of MCMs from the nucleus as S phase proceeds. The dislodged proteins remain in the nucleus in other species, but are unable to bind the chromatin. The MCMs cannot regain access to the origin (or in *Saccharomyces*, the nucleus) until CDK levels fall at the end of mitosis, and Cdc6 and Cdt1 are active again in the next G1 phase.

This sequential requirement for origin binding allows tight cell-cycle regulation of initiation. Low CDK activity allows pre-RC assembly. High CDK activity allows origin firing, but prevents re-assembly of initiation factors. The CDKs, thus, play a dual role by both promoting initiation and preventing re-replication at individual origins.

Origins are also inactivated during times of replication stress, which reduces the risk of catastrophic replication fork collapse and double-strand breaks. This relies on a specific replication checkpoint system. In budding yeast, the Rad53 kinase regulates the Cdc7 kinase to prevent origin activation under these conditions.

Regulating Chromosome Structure during S Phase

The events of S phase are intimately linked to chromosome structure. Cohesion between sister chromatids is established

during S phase, as the sister chromatids are generated. Genetic studies link cohesion to other proteins known to act at the replisome including Ctf4. Cohesion is essential for proper segregation of the chromosomes during mitosis. It prevents chromosome loss, contributes to centromere structure, and helps orient the chromatids to the opposite spindles. Whether the passing replication fork activates the cohesin proteins, or they are activated by the S-phase kinases, remains to be determined.

Chromatin assembly is also affected during S phase. The cell must assemble its newly duplicated DNA into nucleosomes and higher-order chromatin structures. Moreover, any epigenetic modifications on the histones or the DNA must be transferred to the new chromatin. Several conserved complexes are implicated in chromatin assembly and disassembly. The facilitates chromosome transactions (FACT) complex helps to dislodge the DNA from the chromatin and contributes to subsequent reassembly. Studies place FACT in front of the replisome. The chromatin assembly factor (CAF) complex helps recruit new histones into the new DNA. Chromatin structure may, in turn, regulate S-phase timing. Recent studies suggest that modification of histones by acetylation may help determine the timing of firing for individual origins.

Conclusions

Events during S phase have profound effects on chromosome biology throughout the cell cycle. The replication fork has an enormous capacity to remodel chromatin. In addition, activation of specific kinases only during S phase can provide a temporal link between DNA replication and modification of other proteins. Clearly, investigators are only beginning to trace these links. The study of S-phase regulation of multiple chromosome events will expand for years to come.

Glossary

Cdk inhibitors (CKI) There are two families of CKI: the Ink4 family proteins (inhibitors of Cdk4: p15INK4b, p16INK4a, p18INK4c, and p19INK4d) which specifically bind monomeric Cdk4 and Cdk6 to inhibit cyclin D-dependent kinase activity and the Cip/Kip family (p21WAF1, p27Kip1, and p57Kip2) that specifically binds and inhibits cyclin:Cdk complexes (cyclin D:Cdk4/6; cyclin E:Cdk2; and cyclin A:Cdk2).

Cyclin-dependent kinases (Cdk) Key activators of the cell cycle. A group of serine/threonine-specific protein kinase complexes composed of a cyclin regulatory subunit and a Cdk catalytic subunit. Activation of the kinase requires cyclin binding to Cdk.

Restriction point A key cell-cycle transition between the early G₁ mitogen-dependent phase into the late G₁ mitogen-independent phase prior to initiation of DNA synthesis in S phase.

The cell cycle is the process by which one cell becomes two. Somatic cell division involves cell growth (increase in cellular components, such as ribosomes, membranes, and organelles) throughout the cell cycle, faithful replication of its DNA during the S phase of the cell cycle, and precise distribution of DNA between daughter cells during the mitosis (M) phase. In addition, with the exception of early embryonic cell divisions, two gap phases, Gap 1 (G₁) and Gap 2 (G₂), are separated by S phase. As multicellular eukaryote organisms regulate cell division tightly to maintain tissue homeostasis, the most important regulatory decision is made during exiting of the resting state so-called the G₀ phase and G₁ phase of the cell cycle before cells become committed to initiate DNA synthesis and complete the cell cycle.

G₁ and G₀ Phase of the Cell Cycle

The majority of cells in adult metazoans are permanently withdrawn from the cell cycle in a terminally differentiated state. Only small numbers of cells, such as hematopoietic and epithelial early progenitor cells, are actively proliferating. Other cells are reversibly withdrawn from the cell cycle and remain in a quiescent stage or the G₀ phase of the cell cycle. Upon proper stimulation, these cells can re-enter the cell cycle. For example, highly differentiated hepatocytes in adult liver are present in the G₀ resting phase and rarely replicate normally. However, in response to acute liver injury or distress, these G₀ hepatocytes can be stimulated to re-enter the cell cycle and regenerate the liver. Similarly, primary peripheral blood lymphocytes (T and B cells), which are present in the G₀ phase, can re-enter the cell cycle and start clonal expansion when presented with the appropriate antigen. These examples serve to demonstrate that certain cell types may enter and exit the cell cycle pending the appropriate stimulus, whereas the vast majority of cells in a matured metazoan have permanently exited the cell cycle.

The most important decision for cell-cycle progression is made during the G₁ phase. In G₀ phase, cells respond to extracellular signals by entering the G₁ phase of the cell cycle.

However, prior to transiting into the late G₁ phase, they must traverse the growth-factor-dependent restriction point. This is a critical regulatory phase of the cell cycle where a cell becomes committed to enter S phase and finish the remaining cell cycle. In contrast to normal cells, tumor cells are often less growth factor dependent and fail to respond to growth inhibitory signals. Consequently, tumor cells select for genetic mutations that disrupt the important decisions performed at the restriction point and this is, in fact, one of the hallmarks of cancer.

Regulators of G₀ Exit and G₁–S Progression

One of the key negative regulators of the restriction point and early G₁ to G₀ cell-cycle exit is the retinoblastoma tumor suppressor protein (Rb) and two closely related family members, p107 and p130. Murine embryonic fibroblasts (MEF) deficient for all three pocket proteins fail to respond to G₁ phase arrest signals following contact inhibition, serum starvation, or DNA damage. The antiproliferation function of the pocket proteins depends, at least in part, on their interaction with E2F/DP transcriptional factors, which regulate the expression of key genes required for DNA synthesis, DNA repair, DNA-damage checkpoint, apoptosis, and mitosis. Direct interactions of Rb family members with E2F/DP complexes and the recruitment of chromatin-modifying enzyme complexes, such as histone deacetylases (HDAC), polycomb group proteins, the SWI/SNF complex, and histone methyl transferases, to E2F-responsive genes results in inhibition of target gene expression.

Distinct Rb family member–E2F repressor complexes exist in different cell-cycle phases. As an example, during the G₀ phase, p130 and p107 interact with E2F4 and E2F5, whereas Rb remains unbound. E2F4 and E2F5 are expressed constitutively and are involved in E2F-dependent gene repression during cell-cycle exit and terminal differentiation. By contrast, during early G₁ phase, Rb interacts with E2F1, E2F2, and E2F3, the so-called activator E2Fs. When the cell passes through the restriction point, Rb becomes inactivated by hyperphosphorylation, releasing E2Fs 1–3 and promoting the activation of E2F-responsive

genes for cellular proliferation. Recent evidence has shown that the Rb–E2F interaction is a bistable switch, and is necessary and sufficient for restriction point control. Not surprisingly, MEFs deficient for these E2F1, E2F2, and E2F3 exhibit impaired E2F-responsive gene induction in response to serum and significant proliferative defects.

Rb is physiologically regulated by a group of serine/threonine-specific protein kinases called cyclin-dependent kinases (Cdks). Specifically, cyclin D:Cdk4/6 and cyclin E:Cdk2 kinases are responsible for phosphorylating Rb during the G₁ phase of the cell cycle. However, cyclin D and cyclin E are regulated differently and play distinct roles in the cell-cycle regulation of Rb (Figure 1). D-type cyclins are not expressed in G₀ cells. However, cyclin D levels increase after stimulation of growth factors as a result of increased transcription mediated by Myc and Ras/MEK/MAPK signaling pathway and increased stability mediated by the PI(3)K/Akt signaling. In cycling cells, cyclin D levels and associated kinase activity remain relatively constant. Therefore, the D-type cyclins control cell-cycle entrance and exit by linking the mitogenic pathway to the core cell-cycle machinery.

Unlike cyclin D, the expression of cyclin E is mitogen independent and dependent on the action of E2Fs after the hyperphosphorylation and inactivation of Rb at the late G₁ phase of the cell cycle. However, because Rb represses cyclin E expression, questions remain as to how cyclin E gene expression and cyclin–Cdk2 activity is initially turned on. Once cyclin E levels reach a critical threshold, its levels can be further increased as a result of a positive feedback loop. Another potential mechanism of activating Cdk2–cyclin complexes is through the function of a Cdk-activating kinase (CAK). Studies are now being made on identifying this kinase, as it could be a potential target for therapeutics. Recently, a hypothesis has shown that the CAK could be Cdk7, which is known to be

part of the TFIIF transcription complex. However, more studies have to be made in order to substantiate this finding.

Rb undergoes cell-cycle-specific phosphorylation through the distinct phases of the cell cycle and subsequent dephosphorylation during mitosis. In G₀, Rb is unphosphorylated. Unphosphorylated Rb is considered inactive, as it is not able to bind E2F transcription factors. When a cell is stimulated to enter the cell cycle, cyclin D:Cdk4/6 complexes put one phosphate on Rb. This monophosphorylation can occur on at least nine different serines or threonines located throughout Rb. Monophosphorylated Rb is the active, transcriptional-repressing form of Rb and can simultaneously bind to both E2F and HDAC. Once the cell nears the restriction point, Rb is rapidly hyperphosphorylated by cyclin E:Cdk2 to give phosphorylation species of greater than 12 phosphates. This allows for the release of E2F and subsequent transcription of E2F-dependent targets and progression through the cell cycle.

The consequence of cyclin D-dependent and cyclin E-dependent kinase activity on Rb also results in differential regulation. It is apparent that cyclin D-dependent kinases are not sufficient for disrupting the Rb–E2F–HDAC complex. Indeed, this is most dramatically supported by the detection of functional Rb–HDAC–E2F complex in p16^{INK4a}-deficient cancer cells with deregulated and active cyclin D-dependent kinases. Furthermore, in T cells entering the cell cycle, E2F4 associates with Rb only after cyclin D kinase activity is turned on. By contrast, cyclin E-dependent kinase activity and hyperphosphorylation of Rb are required for disrupting E2F–Rb and HDAC–Rb interactions. Moreover, in addition to Rb family members, cyclin E-dependent kinase phosphorylates target proteins involved in chromatin remodeling, DNA synthesis, and centromere functions, further triggering the cell to traverse across the restriction point into late G₁ and S phase.

Figure 1 Model of G₀ and G₁ cell-cycle progression. Activation of cyclin D:Cdk4/6 kinases by growth factor stimulation of G₀ cells results in increased metabolism or growth and monophosphorylation of Rb driving assembly of pRb:E2F complexes. By an unknown mechanism, increased metabolism and cell mass leads to activation of cyclin E:Cdk2 complexes at the restriction point resulting in hyperphosphorylation (inactivation) of Rb, release of E2Fs, and activation of late-G₁-specific genes involved in DNA synthesis and late-G₁-cell-cycle regulation.

Stem Cells and Cell Proliferation

Recent studies have provided an insight into the differences in cell-cycle regulation between somatic and stem cells. Embryonic stem cells have an abbreviated cell cycle and, more importantly, an abbreviated G₁. Mouse embryonic stem cells have constitutive cyclin E:Cdk2 kinase activity, which causes rapid hyperphosphorylation of Rb and subsequent bypass of the restriction point. Thus, embryonic stem cells are not dependent on cyclin D levels and growth factor stimulation. In fact, growing embryonic cells in the presence of MAPK inhibitors will promote self-renewal and prevent differentiation into somatic cells. Less is known about human embryonic stem cells. It has been reported that Cdk4 is upregulated upon reentry into the cell cycle suggesting a dependence on D-type cyclin activity. However, like mouse embryonic stem cells, human embryonic stem cells have a shortened G₁ phase and cell-cycle-independent expression of cyclin E, which leads to hyperphosphorylation of Rb.

Adult stem cells do not proliferate as fast as embryonic stem cells. In fact, about 75% of adult stem cells are quiescent and will enter early G₁ only upon stimulation. Adult stem cells need to proliferate for either self-renewal or differentiation. Knockout of certain markers, such as the Cdk inhibitor p18, cause stem cells to self-renew. Knockout of other markers, such as the gene *HoxB4*, promotes differentiation.

Cell-Growth Regulation

The other aspect of cell-cycle regulation is the increase in cell mass or cell growth. In general, cells must grow to a minimum size to be able to divide and generate two daughter cells equal in size to the starting mother cell. Premature entry into S phase results in smaller daughter cells. Therefore, it has been realized, but not well understood, that generally with the exception of some developmental programs, such as early embryonic cell division and endo-reduplication, cell division and cell growth must be coordinated. Although cell growth is often reflected by an increase in cell size, cell growth needs to be defined as an increase in cell mass, or more precisely, the underlying global RNA and protein synthesis capacity, and additional macromolecule synthesis and storage.

How mitotic cells coordinate cell growth and division remains an open question. Some of the key regulators involved in cell-cycle regulation also control cell growth. For example, the Myc transcription factor has long been implicated in cell-growth regulation in both *Drosophila* and mammalian cells. Besides the gene products involved in cell-cycle regulation, such as cyclin D2, Cdk4, cdc25, cyclin E, and cyclin A, many Myc-target gene products are involved in ribosome biosynthesis, protein synthesis, and specific metabolic pathways. Another example of a key cell-cycle regulator is Rb. In addition to regulating E2F-dependent gene transcription, Rb can also repress RNA polymerase I- and III-dependent transcription that are responsible for the synthesis of ribosomal RNA (rRNA), various small RNAs such as 5S rRNA, and transfer RNA (tRNA). This regulation is mediated by direct interaction of pRb with the upstream-binding factor (UBF) and with the TF-IIIIB coactivator, respectively.

On the other hand, cell growth may influence cell division. Understanding of cell-growth regulation comes from studying

immune-suppressant rapamycin. Treatment of both yeast cells and mammalian cells with rapamycin delays cell growth and proliferation. In budding yeast, signaling of the target of rapamycin (TOR), a protein kinase, coordinates nutrient availability, such as carbon source and nitrogen, with cell growth and proliferation. It turns out that the yeast G₁/S cyclin Cln3 is both translationally and posttranslationally regulated in response to nutrient levels. Cell division occurs when cells reach a certain size. In metazoans, the situation is more complex because nutrient levels are maintained by tissue homeostasis. Not only does mammalian TOR (mTOR) signaling coordinate protein synthesis with glucose and amino acid availability (linked to nutrient sensing signaling pathways), but it also mediates hormonal and mitogenic factor responses. mTOR lies downstream of PI(3) kinase/Akt, although it is currently unclear that they belong to a linear signaling cascade.

PI(3)K/Akt may also activate further downstream targets through tumor-suppressor tuberous sclerosis (TSC) complexes. It turns out that the mTOR pathway in conjunction with signaling through the PI(3)K pathway regulates the translational initiation and elongation, ribosome biosynthesis, amino acid import, and metabolism. One of the important targets in ribosome synthesis regulated by the PI(3)K/Akt/mTOR pathway is S6 kinase, which phosphorylates ribosomal protein S6. In *Drosophila*, S6 is associated with body size and cell growth. S6 phosphorylation is required for the translation of a group of mRNAs with a 5' terminal oligopyrimidine tract (5'TOP), including ribosomal protein messenger RNAs (mRNAs) and mRNAs encoding for translation machinery. In addition, the Akt/mTOR pathway regulates protein translation by phosphorylating and inactivating the translation initiation factor 4E-binding protein (4E-BP1). As a result, PI(3)K/Akt and mTOR are linked to translation initiation by regulating the eukaryotic translation initiation factor 4E (eIF-4E), which enhances the translation of essential genes for cell-cycle regulation, including cyclin D and p27^{Kip1}. Future studies will ultimately resolve how cell growth signaling impinges on and is incorporated into the cell-cycle regulatory machinery.

Future Perspectives

There has been an increased understanding of signal transduction and cell division. A lot of focus has been on protein posttranslational modification and gene expression regulation. However, until recently, the importance of cell growth has not been fully appreciated. Clearly there is cross-talk between cell growth and cell-cycle regulation. Future studies should fill in the gaps in our understanding of cell growth, cell cycle progression, and their subsequent contributions to neoplastic transformation.

Glossary

Apoptosis A form of programmed cell death that kills a cell through condensation, shrinkage, fragmentation, and engulfment of the dead cell fragments by neighboring healthy cells.

ATM A large-molecular-weight protein encoded by the gene that is mutated in the human disease ataxia–telangiectasia (A–T). A–T patients suffer from cerebella degeneration, extreme sensitivity to ionizing radiation, increased cancer risk, and sterility. ATM-knockout mice exhibit most of the A–T phenotypes, except cerebella degeneration. ATM contains a PI3-kinase homology domain and its function is required for ionizing radiation (IR) to activate the cell-cycle checkpoints, apoptosis, and senescence.

ATM and Rad3-related (ATR) A protein with a PI3-kinase homology domain. ATR function is essential to mammalian cells as the knockout of ATR in mice causes embryonic lethality, and the knockout of ATR in cells causes passive death resulting from S-phase defects. ATR is required for the activation of cell-cycle checkpoints induced by UV irradiation.

BRCT A modular protein–protein interaction domain conserved through evolution and found in proteins involved in checkpoint activation and DNA repair.

Checkpoint kinase-1 (Chk1) First identified in the fission yeast and conserved through evolution. DNA damage activates Chk1 to maintain Cdk1/cyclin B (also known as mitosis promoting factor (MPF)) in the latent, inactive state. Chk1 is not an essential gene in yeasts, but Chk1-knockout mouse ES cells die from mitotic catastrophe.

Checkpoint kinase-2 (Chk2) First identified in the fission yeast as the Cds1 kinase and conserved through evolution. The budding yeast contains two Chk2-like kinases: RAD53 and DUN-1. Chk2 also inhibits MPF activation, and it phosphorylates and activates p53.

Cyclin-dependent protein kinase (Cdk) It forms complex with and is activated by cyclin. Cdk1 is also known as Cdc2 kinase.

Cyclins Activators of cyclin-dependent kinases. Cyclins are expressed and degraded periodically through the cell cycle.

DNA damage response (DDR) The cellular machinery that senses DNA damage and activates signaling cascades to promote effector functions comprising checkpoint activation and DNA repair.

FHA A modular protein–protein interaction domain conserved through evolution. FHA domain binds peptides with phosphorylated threonine. The FHA domain is found in a variety of proteins with diverse functions, including those involved in DNA damage signal transduction.

Overview

Error-free DNA replication and chromosome segregation are critical to the maintenance of genome integrity. A variety of DNA lesions are generated during normal metabolic processes or by exposure to external genotoxic agents. To maintain genome integrity, an evolutionarily conserved cellular surveillance network continuously monitors DNA lesions to coordinate DNA repair with cell-cycle progression and cell fate decisions. This surveillance network includes biochemical pathways that act as checkpoints to delay or arrest cell-cycle progression in response to DNA damage. This article discusses three distinct cell-cycle checkpoints that are activated by DNA damage: the G1/S checkpoint, the intra-S checkpoint, and the G2/M checkpoint (Figure 1).

Cell-Cycle Checkpoints Activated by DNA Damage

The G1/S checkpoint inhibits S-phase entry in G1 cells that have not yet committed to DNA replication. The intra-S checkpoint prevents initiation of DNA replication at origins that

have not yet been activated in S-phase cells. The G2/M checkpoint inhibits entry into mitosis. The cell-cycle checkpoints are reversible, allowing resumption of cell-cycle progression after the signals from DNA lesions are extinguished.

The key targets of inhibition by the cell-cycle checkpoint pathways are cyclin-dependent protein kinases (Cdks). Cdks are activated by binding to their cyclin partners, which are strictly controlled by temporally regulated expression, subcellular localization, and ubiquitination-dependent degradation. The kinase activity of cyclin-bound Cdk is further regulated by threonine and tyrosine phosphorylations in the Cdk kinase domain. The DNA damage checkpoint pathways inhibit the expression of cyclins, activate the degradation of cyclins, and promote the inhibitory phosphorylations of Cdks to halt cells in G1 or G2 phases.

The DNA damage checkpoint pathways consist of lesion sensors, adaptors/mediators that assemble signaling complexes at DNA lesions, protein kinases, and their substrate effectors (Table 1). The proteins identified as components of the DNA damage checkpoint pathways are part of the surveillance network that also regulates the orderly progression through an unperturbed cell cycle. Although the G1/S, intra-S,

Figure 1 The cell cycle and DNA damage checkpoints. The cell cycle consists of four distinct phases: G1 phase, S-phase (synthesis), G2-phase, and M-phase (mitosis). Activation of each phase depends on the proper progression and completion of the previous one. The G1-phase is marked by synthesis of enzymes required for DNA replication in S-phase. During S-phase the genome is replicated and the amount of DNA in the cell effectively doubles. During G2 the proteins required for mitosis are produced. Mitosis is the process in which the cell separates the chromosomes into two identical sets in two daughter nuclei. Sequential progression through the cell cycle is regulated by cyclins and cyclin-dependent kinases (Cdks).

Table 1 DNA damage checkpoint proteins

Protein function	Mammals	<i>S. pombe</i>	<i>S. cerevisiae</i>
Sensors			
MRN/X	Mre11/Rad50/ Nbs1	Mre11/Rad50/ Nbs1	Mre11/Rad50/ Xrs2
PCNA-like	Rad9/Rad1/ Hus1	Rad9/Rad1/ Hus1	Ddc1/Rad17/ Mec3
RFC-like	Rad17	Rad17	Rad24
PI3-kinases	ATM ATR (ATRIP) DNA-PK	Tel1 Rad3 (Rad26)	Tel1 Mec1 (Ddc2)
Mediators	Mdc1 53BP1 Claspin BRCA1 TopBP1	Crb2 Mrc1	Rad9 Mrc1
Effector kinase	Chk1 Chk2	Chk1 Cds1	Chk1 Rad53

and G2/M checkpoints are distinct, many of the damage sensors and signaling molecules are shared by all three pathways or play a primary role in one pathway and a back-up role in the others. The checkpoint pathways contain self-reinforcing amplification loops with complex layers of spatial and temporal organization that are still under investigation.

G1/S Checkpoint

Cells in the G1-phase of the cell cycle become committed to enter the S-phase at a stage referred to as the Restriction

point (R) in mammalian cells and Start in budding yeast. The G1/S checkpoint serves to prevent cells from entering S-phase in the presence of DNA damage and functions to inhibit the initiation of replication (Figure 2). In the case of double-stranded breaks (DSBs), caused by ionizing radiation or radiomimetic agents, the ataxia telangiectasia mutated (ATM) kinase is activated and phosphorylates many downstream effectors, notably p53 and Chk2. Activation of these signal transduction pathways serves to initiate (Chk2) and maintain (p53) the G1/S arrest. The initiation of G1/S checkpoint requires Chk1- or Chk2-dependent phosphorylation of the Cdc25A phosphatase, leading to its nuclear exclusion and ubiquitin-mediated degradation. The absence of Cdc25A prevents the dephosphorylation of Cdk2 at the inhibitory phosphorylation sites and thus enforces the inactivation of Cdk2/cyclin complexes. Without active Cdk2, the Cdc45 protein, which is one of the key components of the pre-replication complex, is not phosphorylated and is unable to be loaded onto chromatin to initiate replication. This results in a block to the initiation of DNA synthesis. The phosphorylation-regulated pathway is implemented rapidly in response to DNA damage but is relatively transient and delays G1/S transition for just a few hours. Maintenance of the G1/S arrest requires DNA damage-induced activation of p53, which stimulates the expression of p21/Cip1/WAF1, an inhibitor of Cdk2/cyclin complexes. Since upregulation of p21Cip1 involves transcription and new protein synthesis, this p53-mediated G1 arrest is a slower response that complements the transient acute inhibition of Cdk2 through Cdc25A degradation.

Intra-S Checkpoint

In cells that have passed through the R point and have irreversibly committed to DNA replication, exposure to ionizing radiation activates an Intra-S checkpoint that causes a transient inhibition of DNA synthesis (Figure 2). In eukaryotic cells, the genome is divided into tens of thousands of replicons, each with an origin of replication. The replication origins are not activated synchronously at G1/S transition. Instead, some origins are activated early in S-phase, while others are activated later, with the timing of origin activation being dependent on the chromatin conformation. While DNA damage does not cause S-phase arrest, activation of the checkpoint pathways during S-phase, for example, by DSBs, does cause the inhibition of firing of late origins. The DSB-induced intra-S checkpoint critically depends on the ATM kinase, as illustrated by the radiation-resistant DNA synthesis (RDS) phenotype that characterizes cells lacking functional ATM. Although ATM is required for the activation of the intra-S checkpoint, some other components of the G1/S checkpoint pathway, that is, Chk1, Chk2, CDC25A, p53, and p21Cip1, are not involved in DSB-induced inhibition of late replication origins. Instead, the intra-S checkpoint activation appears to require the ATM-dependent phosphorylation of SMC1 and SMC3, which are components of the cohesin complex that regulates the pairing of sister chromatids. The precise biochemical mechanism underlying the inhibition of late origin firing by ATM and cohesin remains to be elucidated.

Figure 2 Activation and signaling of DNA damage checkpoints. DNA damage triggers a rapid cascade of phosphorylation events initiated by the ATM and ATR protein kinases. ATM is activated by DSBs through the MRN complex that acts the damage sensor. A series of posttranslational modifications, including phosphorylation (P), ubiquitination (Ub), and methylation (M), results in retention of damage proteins at the lesion and activation of checkpoint signaling. ATR is recruited to ssDNA through the ATRIP cofactor that binds RPA and is activated by the 9-1-1 complex, claspins, and TopBP1. The ATM and ATR signaling pathways culminate in the G1/S, intra-S, and G2/M checkpoints. See text for further details.

G2/M Checkpoint

The G2/M checkpoint prevents cells from undergoing mitosis in the presence of DNA damage (Figure 2). Depending on the type of DNA lesion, the ATM-Chk2 pathway and/or the ATR-Chk1 pathway are activated to arrest the cell cycle in G2. In response to UV radiation, the ATR-Chk1 pathway initiates G2 arrest and the ATM-Chk2 pathway maintains the G2 arrest. By contrast, G2 arrest in response to lesions such as ionizing radiation-induced DSBs is initiated by the ATM-Chk2 pathway. Mitotic entry requires Cdc2-mediated dephosphorylation of Cdc2 in complex with cyclin B. The G2/M checkpoint pathways inhibit Cdc2/cyclin B activity by stimulating the inhibitory phosphorylation of Cdc2 through the Wee1 kinase and blocking the dephosphorylation of Cdc2 by the Cdc25 phosphatase. Although it was initially suggested that the Cdc25C phosphatase was the key target of the G2/M checkpoint pathway, it now appears that all three members of Cdc25 family (Cdc25A, Cdc25B, and Cdc25C) cooperate to regulate Cdc2/cyclin B activity. Chk1- or Chk2-mediated phosphorylation of Cdc25 family of phosphatases can induce Cdc25 binding by the 14-3-3 proteins, leading to cytoplasmic sequestration and degradation of Cdc25 by the ubiquitin–proteasome pathway. Other signaling modules that contribute to G2/M arrest include the p38 family of stress-activated protein kinases, the mediators such as 53BP1 and BRCA1, and upstream regulators such as Polo-like kinases (Plk1 and Plk3).

DNA Damage Signal Transduction

DNA Lesion Sensors

The damage surveillance network begins with protein sensors that recognize specific lesions in the genomic DNA (Figure 3). Some of the sensors bind to modified bases, while others respond to nicks, regions of single-stranded DNA (ssDNA), or DSBs. The majority of the lesion sensors are part of the DNA repair pathways. For example, the Mre11/Rad50/Nbs1 (MRN) complex functions as a sensor of DSBs and plays essential roles in both the activation of ATM-dependent checkpoint pathways and DSB repair pathways. Likewise, the MSH2/MSH6 complex functions as a sensor of mismatched, alkylated, or oxidized base pairs and plays essential roles both in the activation of ATM- and ATR-dependent checkpoint pathways and in mismatch repair. The dual roles of lesion sensors in activating checkpoints and repair allow for the coordination of cell-cycle progress with the removal of DNA lesions.

PIKK-Family of Kinases

The two main signal transducers in the DNA damage response are ATM and ATR. They are members of the phosphoinositide 3-kinase-like kinase (PIKK) family and share common domain structure (Figure 4). Another member of the PIKK family involved in regulating cellular

Figure 3 The DNA damage response. Damage lesions in DNA are recognized by sensor proteins that initiate recruit mediators and transducers of the damage response. Signal amplification through effector molecules produces the signaling networks that induce the cellular responses and facilitate repair.

Figure 4 The PIKK family of protein kinases. (a) Schematic of the PIKK domain structure. FAT = FRAP, ATM, TRRAP domain; FATC = FAT C-terminus domain; HEAT = Huntingtin, elongation factor 3, A subunit of protein phosphatase 2A, TOR1. (b) Each PIKK responds to a specific DNA damage lesion. Binding to partner proteins recruits the PIKK to the lesion and interactions with activators induce their full activation and signaling to substrates.

responses to DNA damage is the DNA-dependent protein kinase DNA-PK, although its role in the cell-cycle checkpoint pathways is secondary to its major function in nonhomologous end-joining repair of DSBs. The kinase domain in the C-terminus of these proteins is flanked by the FAT domain and HEAT repeats on the one hand and the FATC domain (required for PIKK kinase activity) on the other (Figure 4). In response to DNA damage, ATM and ATR phosphorylate a large number of cellular proteins at serine and threonine sites in SQ or TQ sequence motifs. ATM is mainly activated by DSBs, while ATR is activated by the exposure of ssDNA. ATM is recruited to DSBs through binding to the MRN complex at DNA ends. ATR is recruited to ssDNA by binding to its partner ATRIP, which associates with the ssDNA-binding protein replication protein A (RPA). A shared sequence motif located at the C-terminus of Nbs1 and the C-terminus of ATRIP has been proposed to be required for recruitment of ATM and ATR, respectively, to damaged DNA.

ATM Activation

ATM is localized predominantly in the nucleus of most cell types, and its levels do not change in response to DNA damage. However, its protein kinase activity is stimulated *in vivo* by agents that induce DNA damage and *in vitro* by linear DNA. The ATM protein is thought to exist in an inactive dimer or higher-order oligomer, and auto-phosphorylation at Ser1981 converts it into monomers, which appear to be the form of the enzyme that activates checkpoint pathways. The MRN complex is important for recruitment of ATM to DSBs and also for its maximal activation. Some substrates of ATM accumulate at the DSBs, whereas others appear only transiently at the damage site, for example, the downstream checkpoint kinase Chk2. Compromising the MRN function (due to inherited hypomorphic mutations, shRNA-mediated knockdown, or viral-mediated inactivation) causes defective ATM auto-phosphorylation and signaling to some downstream substrates. There is evidence that ATM

can also be activated by changes in chromatin structure. ATM auto-phosphorylation can be observed in cells following exposure to hypotonic buffer or by inhibition of histone deacetylases. In addition to MRN, other proteins recruited through ATM interactions, such as Tip60, may also contribute to ATM activation and chromatin modification at DSBs. Stimuli that alter chromatin and induce ATM activation in the absence of DSBs may involve additional ATM-binding proteins, such as ATMIN, that could compete with Nbs1 to interact with ATM.

ATR Activation

ATR is activated during each S-phase in order to regulate replication origin firing and to repair damaged replication forks. While the RPA–ssDNA complex is required to recruit ATR-ATRIP to DNA lesions, it is not sufficient to activate ATR. Functioning at the top of the ATR-signaling network is a heterotrimeric DNA clamp that is conserved from yeast to man. It is structurally similar to the proliferating cell nuclear antigen (PCNA)-homotrimer, and based on the fission yeast gene names (Rad9, Rad1, and Hus1), this trimer is referred to as the 9-1-1 complex. While the PCNA clamp is loaded onto replicating DNA by replication factor C (RFC), the 9-1-1 complex is loaded onto DNA by a specialized clamp loading complex composed of the Rad17 protein (according to the fission yeast gene name) and RFC. Binding of RPA to ssDNA guides the loading of the 9-1-1 complex to the 5' primer end at the ssDNA/dsDNA junctions of resected DSBs or stalled replication forks. The ATR kinase activity is then stimulated by the topoisomerase-binding protein 1 (TopBP1), which is recruited to ATR by binding the C-terminus of Rad9. Therefore, TopBP1 is required for the phosphorylation of ATR substrates and for checkpoint signaling.

Downstream of the ATM and ATR kinases is a network of more than 700 different substrates with a wide range of biological activities and varying degrees of evolutionary conservation. Among the highly conserved substrates are the Chk1 and Chk2 protein kinases that play essential roles in regulating cellular responses to DNA damage. The second group of highly conserved substrates of the ATM and ATR kinases are the mediators, exemplified by Rad9 and Mrc1 proteins in yeast, and the Mdc1 and 53BP1 proteins in mammals. The third group of highly conserved substrates are histones, in particular, the H2AX subunit of the core histones. Phosphorylation by the ATM and ATR kinases generates in these substrates pSQ or pTQ motifs that function as phospho-epitopes in protein–protein interactions that are critical for signaling.

Mediators and Phospho-Dependent Protein-Binding Domains

The transduction of DNA damage signal from the lesion sensors to the protein kinases requires specific phospho-peptide-binding domains, in particular, the forkhead-associated (FHA) and the BRCA1 C-terminal (BRCT) domains. These domains are found in many proteins of the DNA damage network, and they recognize short amino acid sequences flanking phosphorylated serine or threonine residues. The FHA domain binds exclusively to phospho-threonine-containing peptide motifs. FHA folds into a beta-sandwich consisting of two beta sheets. The FHA domain is found in hundreds of prokaryotic and eukaryotic

proteins, including the damage-signaling proteins Mdc1 (a mediator), Nbs1 (a component of the MRN complex), and Chk2. The BRCT domain is often found in tandem repeats in proteins involved in DNA damage signaling and repair, including BRCA1, Mdc1, Nbs1, 53BP1, and DNA ligase IV. Binding to phospho-peptide motifs requires two tandem BRCT domains. The N-terminal BRCT domain stabilizes the phospho-serine, and the C-terminal tandem domain forms a hydrophobic pocket that interacts with the aromatic residue preferentially found at the +3 position in the consensus binding sequence.

Effector Kinases: Chk1 and Chk2

Downstream of ATR and ATM in the cell-cycle checkpoint pathways are two evolutionarily conserved protein kinases Chk1 and Chk2. While ATM and ATR belong to the PIKK family of kinases, Chk1 and Chk2 are members of the protein kinase super-family, but they segregate into different subfamilies of serine/threonine kinases. The Chk1 and Chk2 kinases are directly phosphorylated by ATR and ATM, with Chk1 being primarily activated by ATR and Chk2 by ATM. There is significant crosstalk between the ATR-Chk1 and ATM-Chk2 signaling cascades. The activation of Chk2 is mediated by ATM-phosphorylation-induced multimerization via its FHA domain, resulting in Chk2 auto-phosphorylation and enhanced kinase activity. Interactions with mediator proteins also serve to control the biological activities of the Chk1 and Chk2 kinases through regulation of their subcellular distribution and their stability. As discussed above, the Chk1 and Chk2 kinases negatively regulate the Cdc25 family of phosphatases through phosphorylations to activate the G1/S and the G2/M checkpoints. These effectors also regulate gene expression via phosphorylation of transcriptional activators and repressors, and DNA repair pathways through modification of repair proteins.

Chromatin Modifications

Chromatin modification is an important component of the checkpoint network. Posttranslational modifications on histones, together with chromatin remodeling proteins, facilitate access of repair proteins to damaged DNA and contribute to amplification as well as termination of the damage signal. Phosphorylation of H2AX occurs rapidly in response to damage, and the resulting γ H2AX acts as a platform to recruit and retain signaling and repair proteins. This chromatin landmark plays an essential role in checkpoint activation and chromatin remodeling that involves factors such as INO80, NuA4, and Swr1. Additional posttranslational modifications on H2AX and other histones include tyrosine phosphorylation of H2AX that appears to inhibit ATM/ATR-mediated serine phosphorylation, ubiquitination of H2A and H2AX, sumoylation of H2AZ, tyrosine phosphorylation on H3, acetylation on H2AX, and methylation of histone H4. The pathways leading from DNA lesions to these histone modifications are an active area of investigation.

Spatial and Temporal Organization of the DNA Damage Response

The dynamic redistribution of DNA repair and damage-signaling proteins has been observed in response to the acute

accumulation of DNA lesions. For example, ionizing radiation and radiomimetic drugs induce the formation of nuclear foci (aka IRIF). The techniques of laser micro-irradiation and live cell imaging have been combined to generate spatially defined lesions that facilitate monitoring of the accumulation and phosphorylation of specific proteins to damage sites. Although the current imaging technology may not detect proteins of low abundance and/or proteins that do not accumulate at lesions, they have revealed a series of temporally distinct steps. Immediately following the generation of DSBs, the acetylation and auto-phosphorylation of ATM are observed, concomitant with the phosphorylation of H2AX on Ser139 to generate γ H2AX. Formation of γ H2AX occurs initially near the break site and is then extended outward from the break site for several megabases. The resulting pSQ of γ H2AX is recognized by the tandem BRCT domains of the mediator Mdc1. A repeated pSTD motif in Mdc1 interacts with the FHA and BRCT domains of Nbs1, and facilitates retention of the MRN complex at the break site. The Mdc1 protein is also directly phosphorylated by ATM, and through this phosphorylation event, Mdc1 binds the FHA domain of the ubiquitin ligase RNF8. Recruitment of RNF8 leads to ubiquitination of H2A and H2AX, and the ubiquitinated marks are recognized by RNF168, a second ubiquitin ligase that amplifies the ubiquitination output at the break site. The resulting polyubiquitin chains that accumulate at the break sites further recruit additional factors, for example, the Rap80 protein which contains tandem ubiquitin interacting motifs (UIMs) that bind to polyubiquitin chains. Rap80, together with a coiled-coil scaffold protein Abraxis, mediates the recruitment of BRCA1, another ubiquitin ligase involved in the regulation of homologous recombination and DSB repair. Isopeptidases involved in the breakdown of ubiquitin chains are also part of the complexes assembled at the break sites to regulate DNA damage signaling. The current results suggest that phosphorylation- and ubiquitin-mediated interactions through γ H2AX, Mdc1, ATM, and Nbs1 create a positive feedback loop that amplifies the lesion signals to stimulate repair and cell-cycle checkpoints.

DNA Damage-Induced Apoptosis and Senescence

Under normal physiological conditions, the damage surveillance network coordinates DNA repair with cell-cycle progression to achieve the biological goal of maintaining genome integrity and cell proliferation. The importance of this surveillance network in normal cell growth is best illustrated by the findings that genetic ablation of either ATR or Chk1 cannot be tolerated and leads to cell lethality within one to two cell divisions. The death of ATR-deficient cells cannot be rescued by inactivating the cell death machinery, because the death is rooted in the inability of cells to replicate the genome properly. In contrast to this passive death caused by the loss of ATR, the damage surveillance network can actively stimulate programmed cell death, either in the form of apoptosis that shrinks and breaks a damaged cell or in the form of premature senescence that causes a damaged cell to withdraw irretrievably from the cell cycle.

Unlike the reversible mechanisms of cell-cycle checkpoints, apoptosis and senescence are both irreversible cell fate

decisions. Furthermore, while cell-cycle checkpoints are activated to protect the damaged cell, apoptosis and senescence are activated to destroy the damaged cell. Thus, the DNA damage signaling network has the capability of achieving opposing biological outcomes. Indeed, genetic studies have demonstrated that ATM and Chk2 are required for DSBs to activate cell-cycle checkpoints and apoptosis. The key determinant in the biological outcome downstream of ATM/Chk2 activation is time, because the G1/S, intra-S, and G2/M checkpoints are activated immediately following kinase activation, whereas apoptosis or senescence is invariably a delayed response occurring hours later. The delayed activation of apoptosis or senescence suggests that these biological outcomes may be regulated by the strength and/or the duration of the damage signals.

One of the key effectors in DSB-induced apoptosis or senescence is p53, which is a transcription factor activated by ATM and Chk2. As discussed above, p53 contributes to the maintenance of the G1/S checkpoint by stimulating the expression of p21Cip1 to inhibit Cdk2/cyclin. Activated p53 also stimulates the expression of Mdm2, which ubiquitinates p53 for proteasome-mediated degradation, and this negative feedback loop limits the duration of p53 activation. At doses that do not trigger apoptosis or senescence, a single peak of p53 activity is observed in cells following IR exposure. However, repeated rise and fall in p53 activity is observed in cells treated with IR doses that trigger apoptosis or senescence. These findings suggest that persistent signaling from unresolved DNA lesions causes repeated activation of p53 to trigger the delayed responses. It should be noted that activation of p53 can lead either to apoptosis or to senescence, depending on the cell type. It is therefore important to emphasize that the function of p53 *per se* does not determine the biological outcome following DNA damage. Rather, the strength and the duration of the lesion-induced signal, as well as the cell context, are the critical determinants that control the irreversible cell fate decisions activated by the DNA damage surveillance network.

The ATM-Chk2-p53 pathway is also required for the induction of apoptosis or senescence in response to telomere shortening in somatic mammalian cells. This finding illustrates yet another biological function of the DNA damage surveillance network and underscores the many diseases associated with defects in this signaling network.

Checkpoint Proteins and Human Diseases

Defects in components of the DNA damage response pathways are the underlying causes of a number of human disorders. Cells derived from patients with these disorders have provided valuable reagents to dissect the workings of these pathways. Notably, homozygous mutations in ATM cause ataxia-telangiectasia (A-T), a condition characterized by cerebellar degeneration, immunodeficiency, sterility, genome instability, clinical radiosensitivity, and cancer predisposition. Cells from A-T patients exhibit defects in G1/S, intra-S, and G2/M checkpoints in response to IR. Hypomorphic ATR mutation causing aberrant splicing and partial loss of ATR activity in humans have been associated with the autosomal recessive disorder Seckel syndrome, which shares several clinical features in common with A-T. The Seckel syndrome cells exhibit increased

sensitivity to UV-induced stalling of DNA replication forks and defective G2/M arrest. Hypomorphic mutations in the *NBS1* gene result in Nijmegen breakage syndrome (NBS), a rare autosomal recessive disorder characterized by microcephaly, immunodeficiency, and predisposition to cancer. The most common mutation in NBS patients is 657del5, which results in truncated proteins that maintain some functions of the full-length protein. Hypomorphic mutations in human *MRE11* lead to ataxia-telangiectasia-like disorder (A-TLD), in which patients display ataxia and neurodegeneration, resembling the phenotypes of ATM deficiency. A single patient has been reported with a hypomorphic mutation in *RAD50*, who exhibited phenotypes similar to NBS. Consistent with the involvement of MRN in cell-cycle checkpoint signaling and DNA repair, cells from patients with NBS and A-TLD display increased radio-sensitivity and are defective for checkpoint activation. The RNF168 ubiquitin ligase important for the recruitment of damage-signaling proteins to DSBs is mutated in a syndrome of radiosensitivity, immunodeficiency, and learning difficulty, referred to as RIDDLE syndrome.

With its critical roles in genome maintenance and the destruction of damaged cells, the DNA damage surveillance and response network function as a barrier to neoplastic transformation. Mutations in genes that encode proteins in this network contribute to hereditary and sporadic cancers. For example, germline mutations in p53 or Chk2 are found in Li-Fraumeni syndrome patients, which develop multiple tumors at various organ sites at young age. As discussed above, A-T patients are also prone to cancer development. Other notable tumor suppressors from this network include the mismatch repair proteins, MSH2 and MLH1, BRCA1 and its interacting proteins.

Concluding Remarks

This article describes in broad strokes the basic principles of DNA damage-activated cell-cycle checkpoints. Even at this level of discussion, it is clear that much remains to be deciphered regarding the mechanisms of damage recognition and checkpoint activation. This article focuses on the activation of the checkpoints and its biological consequences, but obviously a complementary complex system exists to terminate the checkpoints and allow cell-cycle progression following DNA repair. Inhibitors of the checkpoint kinases as well as protein phosphatases are likely to be involved in checkpoint termination upon the resolution of DNA lesions or stalled replication

forks. Although little is known about the checkpoint termination processes in mammalian systems, the PP2A phosphatase can regulate ATM phosphorylation in human cells, and phosphatases Wip1/PPM1D may antagonize the activation of Chk1 and Chk2. In addition, ATR-mediated phosphorylation of Chk1 not only activates this protein kinase but also marks it for ubiquitination and proteasomal degradation. Checkpoint termination may also require re-establishment of the original chromatin conformation around the break sites. Independent of signal termination, parts of the checkpoint pathways can be inactivated to restore cell-cycle progression despite the persistence of DNA lesions. The mechanisms underlying checkpoint adaptation to DNA lesions are not completely understood. It is obvious that adaptation would restore cell division at the expense of genome integrity; thus, checkpoint adaptation may promote malignant progression of cancer cells. Since genome integrity is the foundation of normal cellular functions, it will be important to achieve a comprehensive understanding of the DNA damage surveillance and response network.

Glossary

Anaphase-promoting complex (APC) A multisubunit E3 ubiquitin ligase that promotes the proteolytic degradation of substrates such as cyclin B and securin in order for cells to exit mitosis.

Kinetochores A macromolecular complex that is assembled at centromeres near the onset of mitosis that is essential for chromosomes to attach to the spindle.

Kinetochores tension The force that is developed between sister kinetochores because of opposing poleward forces that attempt to separate them.

Monopolar and bipolar States of attachment of chromosomes to either a single pole or to both poles of a spindle.

Wait anaphase signal An inhibitory signal generated from unattached kinetochores that diffuses throughout the cell to block the onset of anaphase.

The mitotic checkpoint is a fail-safe mechanism that evolved to ensure that cells with even a single unaligned chromosome do not exit mitosis to produce aneuploid cells. The mitotic checkpoint solves an inherent problem that arises because of the stochastic nature by which chromosomes attach to the spindle. At the onset of mitosis, chromosomes are randomly distributed throughout the cell so that not all chromosomes will achieve alignment at the spindle equator at the same time. Chromosomes located in the center of the spindle will rapidly establish bipolar attachments due to their higher frequency of encounters with microtubules. By contrast, chromosomes located near a pole will rapidly attach to that pole but attachment to the opposite pole will take more time given the lower frequency that it will find the rare microtubule that originates from the opposite pole. As the kinetochores are the structure on chromosomes that establishes connections with spindle microtubules, the checkpoint monitors this site to determine if chromosomes are properly attached to the spindle and whether it has achieved alignment.

The goal of this article is to discuss current models that explain how the checkpoint monitors kinetochores functions and how a localized defect that is restricted in space can alter the global biochemical status of a cell.

The Mitotic Checkpoint Monitors Kinetochores

The checkpoint is able to sense the status of chromosome alignment by monitoring microtubule occupancy and tension (or the lack thereof) at kinetochores. Once a defect is detected, the kinetochores generate an inhibitory signal to block the onset of anaphase. Early studies showed that a single unattached kinetochores is sufficient to arrest cells in mitosis. Thus, the mitotic checkpoint functions much like a signal transduction cascade where a defective kinetochores generates a signal that must be amplified throughout the cell to inhibit its targets. The discovery of the molecular components of the mitotic checkpoint has shed considerable light into how the mechanical activities at the kinetochores can regulate mitotic progression.

Molecular Components of the Mitotic Checkpoint

The mitotic checkpoint is specified by six evolutionarily conserved genes, BUB1, BUB3, MAD1, MAD2, MAD3, and MPS1. All of these genes are essential as inactivation of any single gene prevents cells from delaying mitosis in the presence of unaligned chromosomes. BUB1 and MPS1 are protein kinases, while the biochemical activities of the remaining proteins are unknown. It appears that MAD3 in metazoans has evolved into BUBR1, a third protein kinase of the mitotic checkpoint. It is interesting that BUBR1 may have co-evolved with centromere protein E (CENP-E), a kinetochores motor whose activity is thought to be monitored by BUBR1 and is also only present in metazoans. With the identification of checkpoint genes, the outstanding question is how their gene products interact at the molecular and biochemical levels to specify the signaling pathway that links a defective kinetochores to inhibition of the anaphase-promoting complex (APC).

Monitoring Microtubule Occupancy and Tension at Kinetochores

The discovery that mitotic checkpoint proteins preferentially localize to unattached kinetochores suggested their roles in monitoring kinetochores activities and generating the wait anaphase signal. In this regard, the role of the MAD2 checkpoint protein at kinetochores has been extensively characterized. Quantitative studies have shown that the staining intensity of MAD2 at unattached kinetochores can be nearly 100-fold higher than that detected at kinetochores that are fully saturated with microtubules. By contrast, the intensity of BUB1 and BUBR1 staining varies only three- to fivefold between unattached and attached kinetochores. It is now evident that MAD2 localization is sensitive to microtubule attachments rather than to kinetochores tension. When microtubule dynamics is suppressed by drugs (taxol or low concentrations of nocodazole or vinblastine) or low temperature, kinetochores are fully attached with microtubules, but no tension develops.

As MAD2 is not detected at these kinetochores, the conclusion was that MAD2 monitors microtubule attachment, but not the tension. These studies therefore reinforced an early notion that kinetochore tension is monitored by the checkpoint.

How tension is monitored by the checkpoint is not fully understood but it clearly involves aurora B/Ipl1, a protein kinase that is situated between sister kinetochores where tension is developed. Recent studies in yeast and mammalian cells showed that aurora B/Ipl1 is required for cells to arrest in mitosis when their kinetochores fail to establish tension despite being saturated with microtubules. Thus, aurora B was found to be essential for cells to arrest in the presence of taxol, a drug that suppresses microtubule dynamics and thus prevents kinetochores from developing tension. Despite this data, auroraB/Ipl1 does not behave like the other checkpoint proteins, as it is not required for cells to arrest in mitosis in response to the loss of microtubule attachments. Aurora B/Ipl1 may therefore provide tension-sensing checkpoint functions.

AuroraB/Ipl1 has been proposed to be part of a mechanism that ensures that improperly attached kinetochores are provided the opportunity to establish proper connections to the spindle. The need for a self-correcting mechanism is evident because of the error-prone nature by which kinetochores establish microtubule connections. Merotelic and syntelic attachments are conditions where both kinetochores are connected to the same pole or when one kinetochore is attached to opposite pole, respectively. As kinetochores with merotelic and syntelic attachments are fully saturated with microtubules, a checkpoint that is only sensitive to microtubule occupancy at kinetochores will fail to detect these aberrant connections. AuroraB/Ipl1 is thought to monitor merotelic and syntelic attachments as these abnormal connections accumulated when this kinase was inactivated. Aurora B/Ipl1 is thought to resolve merotelic and syntelic attachments by stimulating the release of microtubules from these kinetochores and thus promoting new rounds of interactions. Given this scenario, it is possible that kinetochores lacking tension do not directly activate the checkpoint but do so as a result of microtubule detachments that is stimulated by aurora B kinase. This could explain why, in taxol arrested cells, there is on average one kinetochore that exhibits MAD2 staining. It may be possible that this is sufficient to arrest these cells in mitosis.

The mechanism by which aurora B promotes microtubule release from kinetochores has not been clarified but is likely mediated through mitotic centromere-associated kinesin, an unconventional kinesin-like protein that colocalizes with aurora B and functions to depolymerize microtubules.

The Mitotic Checkpoint Monitors a Kinetochore Motor

CENP-E is a kinesin-like protein that binds to kinetochores at the onset of mitosis where it plays a critical role in establishing microtubule attachments. The link between CENP-E and the mitotic checkpoint was first established when cells whose kinetochores were depleted of CENP-E were found to arrest in mitosis. Cells defective for CENP-E functions characteristically accumulate a few chromosomes with monopolar attachments while the majority establish bipolar connections. The inability of monopolar chromosomes to establish bipolar

connections is thought to reflect the importance of CENP-E in allowing kinetochores to capture the rare microtubules that emanate from the opposite pole. On the other hand, chromosomes that are positioned near the middle of the cell can establish bipolar attachments because the higher-frequency encounters with microtubules from both poles can compensate for the loss of CENP-E. Quantitative electromagnetic analysis showed that the bipolar-attached kinetochores lack tension despite attaining near normal numbers of microtubule attachments. By contrast, the kinetochores of the monopolar chromosomes established very few microtubule connections. The defects of the monopolar versus the bipolar-attached chromosomes are viewed differently by the mitotic checkpoint. Consistent with its role in detecting microtubule attachments, MAD2 accumulated at kinetochores of the monopolar chromosomes, while it was undetectable at kinetochores of the bipolar chromosomes. These findings clearly show that the mitotic delay induced by the loss of CENP-E may be due to loss of microtubule attachments and tension.

The precise role of CENP-E in the mitotic checkpoint has been somewhat controversial. Studies in human cells suggested that it was not essential for the checkpoint as cells were able to arrest in the absence of CENP-E. By contrast, *Xenopus* egg extracts depleted of CENP-E and hepatocytes derived from CENP-E null mice failed to delay mitosis in the presence of unaligned chromosomes. The difference in response, however, is most likely a function of whether the assembly of checkpoint proteins to kinetochores is dependent on CENP-E. In egg extracts, the localization of a number of checkpoint proteins to kinetochores was absolutely dependent on CENP-E. Thus, the failure of egg extracts to delay mitosis in the absence of CENP-E can be ascribed to the absence of checkpoint proteins at unattached kinetochores. This contrasts with human cells where checkpoint proteins present at kinetochores that were depleted of CENP-E. However, quantitative analysis showed that in mouse and human cells, CENP-E did affect the assembly of checkpoint proteins at kinetochores. In both species, kinetochores depleted of CENP-E had approximately two- to fourfold lower levels of MAD1, MAD2, and BUBR1 than normal. However, this did not resolve why mouse cells failed to arrest in mitosis in the absence of CENP-E while human cells arrested. The discrepancy could be resolved if we take into account the fact that far fewer monopolar chromosomes accumulated in CENP-E depleted mouse cells than in human cells (two vs. eight). Given that the reduction in the amount of checkpoint proteins at these kinetochores likely compromised their ability to generate the wait anaphase signal, the combined output from all of the unattached kinetochores in mouse cells may not reach a threshold level that is required to sustain a prolonged arrest. In human cells, this threshold may be achieved as a result of the higher numbers of unattached kinetochores. Indeed, both mouse and human cells depleted of CENP-E were able to arrest in mitosis if the number of unattached kinetochores were increased by using drugs that inhibit spindle formation.

The mechanism by which CENP-E function is monitored by the checkpoint is believed to be mediated by the BUBR1 kinase. This connection was uncovered when hBUBR1 was identified in a yeast two-hybrid screen for proteins that interacted with CENP-E. This interaction was subsequently validated

Figure 1 BUBR1 kinase acts as a mechanosensor that monitors centromere protein E (CENP-E) at kinetochores. BUBR1 kinase (green) interacts near the carboxy-terminus of CENP-E where it is postulated to monitor the microtubule-binding status of CENP-E. In the absence of microtubule attachments, BUBR1 is phosphorylated and activated (green oval) so that it generates the wait anaphase signal. When CENP-E is properly attached to microtubules, it undergoes a conformational change that inhibits BUBR1 kinase (green triangles) and thus extinguishes the wait anaphase signal.

when CENP-E and hBUBR1 were found to form a complex in cells. This finding coupled to the fact that hBUBR1 is an essential checkpoint protein suggested that hBUBR1 might act as a mechanosensor to monitor the activities of CENP-E at kinetochores (Figure 1). Consistent with this, hBUBR1 was found to be required for cells to arrest in mitosis when CENP-E functions were inhibited. The mechanism by which hBUBR1 monitors CENP-E activity remains to be clarified, but the working hypothesis is that hBUBR1 kinase activity is sensitive to interactions between CENP-E and microtubules. In the absence of microtubule interactions, CENP-E assumes a conformation that stimulates hBUBR1 to generate the wait anaphase signal. When CENP-E is interacting productively with microtubules, then hBUBR1 is silenced. Recent *in vitro* data showed that both *Xenopus* and human CENP-E can directly bind to BUBR1, and this binding stimulated its kinase activity. As microtubules were not present in these reactions, it is possible that the interaction reflected the checkpoint-on state. Addition of a CENP-E antibody to the CENP-E:BUBR1 complex inhibited kinase activity without disrupting the complex. The interpretation of this finding was that antibody binding altered the conformation of CENP-E so that it was unable to stimulate BUBR1 kinase activity. Thus, kinase activity of BUBR1 may be regulated allosterically by different conformational states of CENP-E. Although this model may indeed apply to the situation *in vivo*, the exact details of the mechanism remain to be clarified. For example, the *in vitro* dependence of BUBR1 kinase activity on CENP-E does not account for how cells that are depleted of CENP-E arrest in mitosis.

Inhibition of Mitotic Exit by the Checkpoint

Checkpoint proteins are functionally complex as they participate in multiple steps along the checkpoint-signaling pathway. A confluence of genetic and biochemical studies showed that the target of the checkpoint is the APC, an E3 ubiquitin ligase that promotes the degradation of substrates that inhibit the onset of anaphase.

Figure 2 Sequestration model. The MAD2 checkpoint protein (purple semicircle) transiently binds to unattached kinetochores (red ovals) where they are converted to a form that upon dissociation will bind to CDC20. CDC20 when associated with MAD2 is incapable of activating the anaphase-promoting complex (APC). In this model, the pool of MAD2 that is released from kinetochores acts as the wait anaphase signal by indirectly preventing the activation of APC.

Sequestration Model

Studies in budding and fission yeast identified checkpoint-defective alleles of CDC20/Slp1, a protein that was shown biochemically to recruit substrates to the APC. These CDC20 and Slp1 mutants were unable to bind to MAD2 and thus supported *in vitro* data that MAD2 can inhibit the ubiquitin ligase activity of CDC20-dependent APC. These findings coupled with the *in vivo* observation that MAD2 exhibited a rapid rate of turnover at unattached kinetochores led to a model that described how MAD2 might act as the diffusible wait anaphase signal. In this sequestration model, unattached kinetochores are thought to catalytically convert MAD2 into an activated state, which upon release from kinetochores binds to CDC20 and sequesters it from the APC (Figure 2). The existence of an activated MAD2 initially gained support when it was discovered that recombinant MAD2 existed as monomers and oligomers (di- and tetramers), but the oligomeric form was more potent at inhibiting APC than the monomeric form *in vitro*. However, the existence of a MAD2 oligomer *in vivo* has been elusive. Furthermore, MAD2 mutants that failed to form tetramers *in vitro* were found to be well tolerated in yeast. These data suggest that if an activated MAD2 does exist *in vivo*, it is unlikely to be a tetramer.

Indeed, structural studies showed that MAD2 adopts two conformations that are either active or inactive. O-MAD2 is the open conformer that is inactive while the C-MAD2, closed conformer, exhibits checkpoint activity. The two conformers exhibit distinct structures mainly at the N- and C-termini of the molecules, specifically in the arrangement and position of two C-terminal β -strands and connecting loops. When MAD2 is bound to either MAD1 or CDC20, this region adopts a closed safety belt-like loop that defines the C-MAD2 conformer. Although the predominant conformer in cells is usually O-MAD2, during mitosis a MAD1:C-MAD2 complex that is present at unattached kinetochores is believed to catalytically convert the cytosolic pool of O-MAD2 into C-MAD2. In this template model, C-MAD2 is generated at kinetochores and, upon its release, it can form CDC20:C-MAD2 complexes that

may further amplify the production of C-MAD2 by converting additional molecules of O-MAD2.

A MAD2 dimerization domain, mainly involving residues at its α C helix (122–142 residues in human MAD2), is fundamental in mediating the O to C-MAD2 conversion. However, the rate at which O-MAD2 spontaneously converts into C-MAD2 is very slow. Thus, recombinant wild-type MAD2 consists largely of the O-MAD2 monomer, with small amounts of O:C heterodimer and C:C homodimer. Acceleration of the O→C conversion has been achieved *in vitro* with purified liganded C-MAD2, in the form of MAD1:C-MAD2 or CDC20:C-MAD2 complexes. This conversion depends on transient O:C heterodimerization. Liganded C-MAD2 seems incapable of forming C:C homodimers due to steric clashes at the MAD2 dimerization interface. Interestingly, p31^{comet}, a negative regulator of the mitotic checkpoint, was shown to exploit the dimerization interface to block O→C-MAD2 conversion during mitosis. Through structural mimicry, p31^{comet} binds to C-MAD2 at the α C helix thus preventing access of O-MAD2 for C-MAD2 amplification. Recent results also suggested that p31^{comet} may function downstream of the O→C conversion step during mitotic checkpoint signal transduction. The key question is to understand how p31^{comet} activity is regulated so that it knows when it is needed to silence the checkpoint to promote mitotic exit.

The CDC20:C-MAD2 interaction was thought to represent the terminal step of the mitotic checkpoint pathway, by sequestering CDC20 from APC/C activation. However, the long-known association of MAD2 with core APC/C subunits is inconsistent with the simple sequestration model. Although C-MAD2 is clearly essential for checkpoint activity, a mathematical model taking into consideration all known biochemical properties of C-MAD2 predicted that >5 h would be required to sequester 50% of intracellular CDC20. As an unperturbed mitosis is completed (onset of anaphase) within

30–40 min of mitotic entry, additional mechanisms must exist for rapid and efficient APC/C^{CDC20} inhibition. The checkpoint protein BUBR1 displays higher affinity toward CDC20 compared to MAD2 and has also been proposed to sequester CDC20 from APC/C. However, as with MAD2, BUBR1 alone is unable to inhibit pre-assembled mitotic APC/C^{CDC20} holoenzyme at physiologically relevant concentrations.

Direct Inhibitor Model

The direct inhibitor model differs from the sequestration model in that the APC is directly inhibited by checkpoint proteins and posits that the unattached kinetochore may sensitize the APC to its inhibitor (rather than generating a factor that sequesters an activator of the APC) (Figure 3). This model originated from the discovery of the mitotic checkpoint complex (MCC), a factor that was identified by testing fractionated cell extracts for inhibitory activity against mitotic APC. The MCC was originally identified in Hela cells, where it was found to consist of near stoichiometric amounts of hBUBR1, hBUB3, CDC20, and MAD2. The interesting finding was that the MAD2 that was present in the MCC represented a very small fraction (<5%) of the total pool of MAD2. Despite the presence of a large pool of monomeric MAD2, this pool was not found to inhibit the mitotic APC. Furthermore, MCC was more than 3000-fold more potent inhibitor of the APC than recombinant MAD2 (which was used in all the previous studies). The large difference in the inhibitory activities suggests that Hela cells do not express sufficient amounts of monomeric MAD2 to inhibit the APC. The mechanism by which MCC inhibited APC activity is not clear but is likely to depend on its ability to bind to the APC. When purified from cells, APC that was associated with MCC was found to be inactive, while

Figure 3 Direct inhibition model. BUBR1, Bub3, CDC20, and MAD2 form the mitotic checkpoint complex (MCC), which binds and directly inhibits the APC. Formation of MCC depends on C-MAD2, which is generated from O-MAD2 through its conversion at kinetochores (red ovals). Once kinetochores have established proper attachments to the spindle, p31^{Comet} is activated in an unknown way to block the O to C conversion. Loss of C-MAD2 production leads to disassembly of the MCC (stippled) and release of the APC from checkpoint inhibition.

APC that lacked MCC was highly active. Based on these findings, the MCC was proposed to be the primary checkpoint inhibitor of the APC in mitotically arrested cells.

Although MCC was identified in mitotic HeLa cells, it was also reported to be present and active throughout the cell cycle. As kinetochores are only present in mitosis, the existence of MCC during interphase suggested that MCC formation occurred independently of kinetochores. More recent studies, however, established that MCC is formed only in mitosis, but subcomplexes of BubR1/Bub3 and BubR1/Bub3/Cdc20 are detected as cells progress from early to late stages of interphase (G1 through G2), respectively. Why MCC formation occurs through intermediates consisting of BubR1/Bub3 to BubR1/Bub3/Cdc20 and, finally, BubR1/Bub3/Cdc20/Mad2 remains unclear. The latest findings show that MCC formation is dependent on kinetochores, and the previously reported APC inhibitory activity of interphase MCC was likely mediated by intermediates of MCC (BubR1/Bub3/Cdc20).

The existence of the MCC has been confirmed in other species including *Xenopus* and yeast. Nevertheless, the connection between MCC and the wait anaphase signal (C-MAD2 in particular) has only been postulated but not experimentally established. In fact, discrepancies in the description of the MCC has clouded its role in the checkpoint pathway. The discrepancies included whether MAD2 was part of the MCC, and whether MCC formation was dependent on unattached kinetochores. Differing reports claimed no or only substoichiometric amounts of MAD2 associated with BUBR1 or APC/C; and whether MCC formation was detected in interphase cells or its formation was independent of unattached kinetochores.

These issues were recently resolved with the discovery that MCC selectively recruits only C-MAD2. These studies were initiated because many of the reports that claimed MCC did not contain MAD2 relied on experiments that used wild-type MAD2, which exists predominantly in the inactive O-conformer. The availability of a collection of MAD2 mutants that were locked in either the O or C-conformers, in combination with dimerization defective mutants, prompted a systematic analysis of MCC formation. Both *in vivo* and *in vitro* data established that MCC selectively incorporated C-MAD2, more specifically, C-MAD2 homodimers (see below). As C-MAD2 is generated from kinetochores, it explains how MCC formation is limited to mitosis. The selectivity of C-MAD2 for the MCC also clarifies discrepancies among earlier reports regarding the presence and amounts of MAD2 in the MCC. Differences in MAD2 levels reported in MCC preparations may be ascribed to variable O:C ratios of MAD2^{WT} that exist in those preparations. MAD2^{WT} is composed of both O- and C-conformers at steady state, but as the O-conformer is the predominant topological form *in vitro* and *in vivo*, the majority of MAD2^{WT} would not be expected to be part of the MCC. Based on our current data, the MAD2^{WT} present in the MCC isolated from cells or assembled *in vitro* represents the small fraction of C-conformer.

Several lines of evidence from these studies showed that incorporation of C-MAD2 into the MCC stimulated both its binding and inhibition of APC/C. The results are in agreement with the original report that partially purified MCC displayed potent inhibitory activity toward mitotic APC/C than recombinant Mad2 alone. Recently, Herzog et al. demonstrated that in

HeLa cells that were arrested in mitosis, APC/C existed either as apo-APC/C, that lacked the CDC20 activator, or as a supra-complex with MCC containing MAD2. The apo-APC/C might be due to sequestration of CDC20 by C-MAD2 and BUBR1:BUB3 complex, but MCC provides an added layer of inhibition by targeting APC/C^{CDC20}.

The finding that C-MAD2 homodimers are incorporated into the MCC may shed light on the control mechanisms for silencing the mitotic checkpoint. Although homodimers of C-MAD2 have been reported, the functional role of this complex has remained enigmatic. This is due in part to structural studies that suggest that a C-MAD2 homodimer is incapable of catalyzing the conversion of O-MAD2. A role of the homodimer in MCC formation not only provides a functional role for this complex, but also fulfils a prediction based on mathematical modeling. Sear and Howard suggested the existence of two species of APC/C inhibitors to satisfy the time spans observed for both checkpoint activation and inactivation. Their model predicted that one species is dependent upon unattached kinetochores and is auto-amplifiable. C-MAD2 fulfils these criteria, but the calculations estimated that it would take >5 h for sufficient C-MAD2 to be made to sequester the cellular pool of CDC20. The model predicted the existence of a second species of inhibitor that would allow timely activation and inactivation of the checkpoint inhibitory signal. The model predicted that the second species is derived from the first species, but is incapable of auto-amplification. The C-MAD2 homodimer could be the second inhibitor given that it has been found to be part of the MCC. In accordance with the model, C-MAD2 homodimer sustains potent APC/C inhibitory activity but cannot generate more inhibitors (O to C-MAD2 conversion). If the affinity constant for the interaction between BUBR1 and C-MAD2 homodimer is relatively low, it ensures that MCC will disassemble when the production of C-MAD2 is halted after kinetochores have satisfied the checkpoint. On the other hand, it is more likely that separate mechanisms that disassemble MCC and its association with the APC/C may involve ubiquitylation of CDC20 or other ATP-dependent processes.

These latest findings resolve discrepancies regarding the existence of the MCC. These studies also confirmed that formation of the MCC occurs only in mitosis, and is therefore likely to depend on kinetochores. This eliminates an earlier model that suggested that MCC formation was independent of kinetochores.

Dual Roles for Mitotic Checkpoint Proteins

The discovery that the MCC contains proteins that are also localized at kinetochores suggested that they might play dual roles in the checkpoint. These proteins participate in monitoring kinetochore defects and then generating the wait anaphase signal. The same proteins also act downstream of the kinetochore by being part of the MCC that directly inhibits the APC.

Early studies of the human BUBR1 kinase showed that its kinase activity was essential for the mitotic checkpoint. Nevertheless, hBUBR1 purified from interphase cells as part of the MCC exhibits no detectable kinase activity, yet is fully capable of inhibiting APC. Likewise, *in vitro* studies showed that

inhibition of the CDC20-dependent APC activity by recombinant BUBR1 can also be independent of its kinase activity. The apparent contradictory findings could be resolved by postulating that kinase activity of BUBR1 was required for the kinetochore while kinase activity was not required for downstream components such as the MCC. This hypothesis has now been confirmed in *Xenopus* egg extracts by BUBR1 depletion and add-back experiments. When extracts depleted of BUBR1 are reprogrammed with a kinase-dead mutant, they are no longer able to activate their checkpoint. Interestingly, if the BUBR1 (wild type or mutant) was supplemented to 20% of the endogenous level, it is sufficient to saturate all the kinetochores to levels seen in normal kinetochores. However, the presence of BUBR1 at kinetochores is still insufficient to activate the checkpoint unless the cytosolic pool of BUBR1 is also restored. This suggests that BUBR1 might provide two separable functions in the checkpoint. Whether the cytosolic BUBR1 acts by sequestering CDC20 or as part of the MCC is not clear. The finding that either wild-type or kinase-dead BUBR1 can restore the checkpoint to kinetochores that had assembled BUBR1 wild-type kinase but not the mutant supports the idea that its kinase activity was essential at kinetochores but not in the cytosol.

Wait Anaphase Output Regulated by Checkpoint Proteins

Studies of hNuf2 and CENP-I led to the remarkable finding that MPS1, MAD1, and MAD2 do not appear to play an essential role at the kinetochore. How do kinetochores that lack MPS1, MAD1, and MAD2 maintain the checkpoint? This is most likely achieved in part by BUBR1 and BUB1 whose levels were not noticeably depleted. However, these proteins by themselves do not appear to be sufficient to generate a robust wait anaphase signal from unattached kinetochores. Cells defective for CENP-I accumulate a few monopolar chromosomes, while most chromosomes appear aligned (similar to loss of CENP-E). These cells are unable to sustain a prolonged mitotic arrest because the unattached kinetochores cannot generate sufficient amounts of wait anaphase signal to sustain a prolonged arrest. Consistent with this explanation, if the total number of unattached kinetochores was increased by disrupting the spindle with microtubule poisons, the collective output from a large number of unattached kinetochores must reach a critical threshold that is required for cells to arrest in mitosis. The caveat of this interpretation is that, after nocodazole treatment, kinetochores depleted of CENP-I exhibited detectable MAD2, although it was 20-fold lower than the level that is present at in-control cells. Nocodazole-treated

Hela cells easily contain more than 20 unattached kinetochores (Karyotype >60 chromosomes) and should therefore be able to generate a threshold level that can normally be achieved by a single unattached kinetochore.

Glossary

Calpains A family of Ca^{2+} -activated proteases that mediates some of the physiological effects of Ca^{2+} signals but that can also mediate cell death. Substrates include cytoskeletal proteins, other proteases, and Ca^{2+} transport proteins.

Caspases Cysteine aspartases that are activated during inflammatory processes and in apoptosis.

NCX The sodium–calcium exchanger that operates the transport of these two ions depending on their electrochemical gradients.

Plasma membrane Ca^{2+} pump ATPase (PMCA) Transmembrane Ca^{2+} pump that uses ATP to pump Ca^{2+} out of cells.

Various genetically encoded programs involved in the signaling, initiation, and execution of cell death decide cells' fate during development and adult life. These programs can execute physiological cell death during development or tissue turnover, and are also involved in the inappropriate elimination of cells under pathological conditions. Because balanced cell turnover is essential for life, defects in cell elimination can also result in disease, the foremost example being cancer. In many circumstances, both physiological cell death and cell death in pathological settings have similar morphological and biochemical characteristics. Perhaps the best-characterized biochemical and morphological changes during a cell death program are those defined as apoptosis. Apoptosis is characterized by condensation and fragmentation of the nucleus with shrinkage of the cytoplasm and exposure of surface molecules that facilitate recognition of the dying cells by phagocytes. However, other types of cell death are present and are strictly regulated *in vivo*, including cell lysis/necrosis or autophagy. Imbalance in cellular calcium regulation has been involved in both apoptotic and nonapoptotic cell death. Calcium can be a signal for cell death or simply a downstream consequence of the activation of the death machinery.

Ca^{2+} as a Signal for Cell Death

A sustained Ca^{2+} overload, such as that resulting from dysfunction of the main routes of Ca^{2+} entry or efflux or from the irreversible loss of intracellular buffering capacity, can be lethal. The idea that Ca^{2+} may be cytotoxic dates back to A Fleckenstein's suggestion in 1968 that excessive entry of Ca^{2+} into myocytes could be the underlying mechanism of cardiac pathology following ischemia. Subsequent studies showed that agonist stimulation or cytotoxic agents could cause lethal Ca^{2+} entry into cells. Cellular Ca^{2+} overload involves multiple intra- and extracellular routes, most of which are also used for physiological signaling, which implies that not only alterations of the normal Ca^{2+} homeostasis but also changes in Ca^{2+} signaling can have adverse effects. The following have been shown in a large number of experimental paradigms: (1) direct sustained elevation of $[\text{Ca}^{2+}]_i$ (e.g., by exposure of cells to ionophores or

to conditions that cause prolonged gating of inward-directed channels) causes cell death; (2) a $[\text{Ca}^{2+}]_i$ elevation precedes cell death induced by pathophysiological stimuli; (3) prevention of $[\text{Ca}^{2+}]_i$ elevation during such experiments can inhibit cell death; and (4) alterations of Ca^{2+} -signaling pathways (e.g., potentiation or inhibition of Ca^{2+} currents) can result in cytotoxicity.

Executors of Ca^{2+} Death Signals

Intracellular Ca^{2+} signals can set off cell demise via Ca^{2+} -dependent processes, change the mode of cell death from apoptosis to necrosis, or synergize with elements of the apoptotic death program. In particular, Ca^{2+} -activated proteases (calpains) can synergize with caspases and amplify apoptotic death routines, while modulators of apoptosis such as members of the Bcl-2 protein family can modulate Ca^{2+} compartmentalization. Hydrolytic enzymes, which include calpains, various DNases, and lipases, are the best-characterized effectors of cell death directly mediated by calcium overload. Calpains are Ca^{2+} -activated cysteine proteases that have been implicated in toxic cell death in the liver and in excitotoxic neuronal death. Calcium-dependent DNases can be responsible for DNA degradation, although the nature of the Ca^{2+} -dependent enzyme(s) responsible for the typical oligonucleosomal DNA cleavage has remained elusive. Among lipases, the Ca^{2+} -dependent phospholipase A_2 (PLA_2) has been implicated in neurotoxicity. Its activation results in the release of arachidonic acid and related polyunsaturated fatty acids, which are further metabolized by lipoxygenases or cyclooxygenases with concomitant generation of reactive oxygen species. In addition, PLA_2 activation generates lysophosphatids that alter the membrane structure, which may facilitate Ca^{2+} influx and Ca^{2+} release from internal stores.

Ca^{2+} , Excitotoxicity, and Death during Brain Ischemia

Excitotoxicity is a phenomenon typically encountered in neurons or myocytes following receptor stimulation by excitatory

amino acids that exceeds the physiological range with respect to duration or intensity. Typical excitotoxic stimulators are capsaicin, acetylcholine, or – most important in the central nervous system – glutamate. Direct injection of glutamate is selectively neurotoxic *in vivo*. Also, inhibition of excess synaptic activity by inhibitors of glutamate receptor subtypes (mainly *N*-methyl-D-aspartate, or NMDA) protects neurons from hypoxia. Generally, excitotoxicity is induced by conditions favoring glutamate accumulation in the extracellular space. Typical conditions leading to increased extracellular glutamate concentration are depolarization of neurons, energy depletion due to hypoglycemia or hypoxia, or defects in the glutamate reuptake systems.

Overall, three different lines of evidence suggest the key role of Ca^{2+} in excitotoxicity: (1) There is an obvious increase in intracellular Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) in both *in vivo* and *in vitro* models of excitotoxic cell death. This has been observed in ischemic brain and in brain slices exposed to NMDA agonists or anoxia. In addition, glutamate-stimulated Ca^{2+} influx in cultured neurons has been shown by the Ca^{45} technique, and increased $[\text{Ca}^{2+}]_i$ after NMDA stimulation has been observed repeatedly using fluorescent probes. (2) Prevention of Ca^{2+} entry into the cell by removal of extracellular Ca^{2+} depletion of NMDA or by pharmacological inhibition of glutamate receptors or voltage-dependent Ca^{2+} channels prevents neuronal death in many paradigms of excitotoxicity. (3) Prevention of neurotoxicity by inhibition of downstream effects of Ca^{2+} overload strongly suggests a causal role of Ca^{2+} in excitotoxicity. Intracellular Ca^{2+} chelators can prevent ischemic damage *in vivo* and excitotoxic neuronal damage *in vitro*. Also, inhibition of effectors of Ca^{2+} toxicity such as calmodulin, calcineurin, and bNOS protects neurons from the toxicity of excitatory amino acids. On the other hand, there could potentially be other routes for Ca^{2+} entry under excitotoxic conditions.

Using a model of hypoxia (oxygen/glucose deprivation, or OGD), a new lethal pathway that involves the activation of a cation conductance (I_{OGD}) has recently been unveiled. This leads to neuronal Ca^{2+} overload in the absence of excitotoxic stimulation. I_{OGD} requires the TRMP7 ion-channel protein, a member of the TRP (transient receptor potential) cation channel super family. Gating of TRMP7 occurs because of the generation of an excess of reactive oxygen/nitrogen species in anoxic neurons. Because gating TRMP7 allows Ca^{2+} entry into the neuron and Ca^{2+} can stimulate further radical production, a vicious loop leading to sustained Ca^{2+} overload is established in the absence of NMDA-R stimulation by excess glutamate.

In addition to excessive entry of Ca^{2+} through membrane channels, mitochondrial Ca^{2+} sequestration and subsequent release play a central role in ischemia- or glutamate-mediated cell death. Nevertheless, mitochondrial Ca^{2+} release and increased Ca^{2+} influx into neurons cannot fully account for the irreversible buildup of intracellular Ca^{2+} after excitotoxic stimulation. The bulk increase in cellular Ca^{2+} should be rectified over time, unless cellular Ca^{2+} extrusion is inhibited. Inhibition of cellular Ca^{2+} efflux from cells is sufficient to trigger cell death in non-neuronal cells, and in neurons may be brought about by oxidative damage downstream of mitochondrial dysfunction. Recent work shows that calpains can cleave the plasma membrane $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) in brain ischemia and in cerebellar granule neurons exposed to

glutamate. Calpain-mediated NCX proteolysis is necessary for the delayed excitotoxic Ca^{2+} deregulation leading to neuronal death (for a schematic summary of excitotoxicity, see Figure 1).

Apoptosis, Necrosis, and Other Ca^{2+} -Dependent Forms of Cell Death in Brain Ischemia

Neuronal demise and neurological dysfunction in brain ischemia are clearly due to several components. Apoptosis and necrosis, in their classical definition, are two fundamentally different modes of cell death. Whereas apoptosis is characterized by a preservation of membrane integrity until the cell is phagocytosed, this is not the case in necrosis/lysis of cells. The duration and extent of Ca^{2+} influx may determine if neurons survive, die by apoptosis, or undergo necrotic lysis. Very low $[\text{Ca}^{2+}]_i$ or the prolonged inhibition of Ca^{2+} influx may be neurotoxic. A continuous moderate increase in $[\text{Ca}^{2+}]_i$, such as that produced by a sustained slow influx, may cause apoptosis, whereas an exceedingly high influx causes rapid cell lysis. For example, stimulation of cortical neurons with high concentrations of NMDA results in necrosis, whereas exposure to low concentrations causes apoptosis. Accordingly, neuronal death in experimental stroke models is predominantly necrotic in the ischemic core, but apoptosis occurs in the less severely compromised penumbra or border regions. The same applies to several other neuropathological conditions in which apoptosis and necrosis have been observed to occur simultaneously. One sensor that switches neurons toward one of the two fates is the ability of cells to generate adenosine triphosphate (ATP). A complete de-energization of the cell (e.g., failure of all mitochondria and of glycolysis) does not allow the ordered sequence of changes required for the apoptotic demise. In such a case, other processes result in rapid, uncontrolled cell lysis/necrosis. Therefore, under conditions of Ca^{2+} overload, apoptosis ensues when sufficient energy production (ATP) is available to execute the death program. The main ATP-requiring step for the execution of apoptosis is the formation of the apoptosome protein complex between cytochrome *c* released from damaged mitochondria, the cytosolic protein APAF-1, and procaspases. Either ATP or dATP is required to promote the functional activation and assembly of this complex, which then leads to caspase activation and cell breakdown.

Ca^{2+} Signals in Neurodegenerative Disorders

Neurons rely on complex synaptic activity to function and substantial loss of synapses can lead to neurodegeneration. The initial proposal that excitotoxic mechanism may contribute to neurodegenerative disorders including Alzheimer's and Parkinson's diseases has fostered intense research on the possible role of Ca^{2+} signaling dysfunction during early stages of neurodegeneration. Recent work has highlighted defects in calcium transport and release from the endoplasmic reticulum (ER) in mouse models of Alzheimer's diseases as well as relevant Ca^{2+} signal alterations at synapses. For example, deficits in NMDARs function at synapses of young Alzheimer's disease mice have been associated with increased ryanodine receptor activity. Abeta oligomers can cause localized calcium elevation and tau missorting in dendrites followed by disruption of

Figure 1 The term neuronal excitotoxicity defines as consequences of excessive stimulation of postsynaptic glutamate receptors. Excess glutamate in the synapse causes gating of AMPA and NMDA receptors. The former allows entry of Na^+ and Ca^{2+} into the neuron. Na^+ hyperpolarizes the plasma membrane and removes the Mg^{2+} block from the NMDA receptor (the NMDA receptor is normally 'plugged' by Mg^{2+}). The NMDA receptor is then gated to Ca^{2+} that flows into the neuron. Additional routes for Ca^{2+} entry involve the TRPM7 cation channel and voltage-operated Ca^{2+} channels. Ca^{2+} accumulates in mitochondria as amorphous calcium phosphate. When the buffering capacity of mitochondria is overwhelmed, Ca^{2+} is released in a process known as permeability transition (PT). Efflux of Ca^{2+} from the neuron is operated by the NCX and the PMCA. When mitochondria release their Ca^{2+} and the efflux systems are unable to extrude the excess intracellular Ca^{2+} , Ca^{2+} overload becomes irreversible and causes neuronal demise.

microtubules and spines. It is apparent that synaptic dysfunction either caused by alterations in Ca^{2+} signaling or leading to alterations in Ca^{2+} transport can enhance synaptic pruning and lead to a loss of plasticity. Both these events feature prominently in age-related neurodegenerative disorders including dementia and motor disorders.

Ca^{2+} Signals as Subroutines of the Apoptotic Program

The role of Ca^{2+} in apoptosis signaling was initially suggested by studies in thymocytes and lymphocytes showing that sustained Ca^{2+} increases could trigger the DNA fragmentation typical of apoptosis and all the other features of the apoptotic demise. Ca^{2+} may be central in the unfolding of the apoptotic program at different stages. Ca^{2+} -mediated mitochondrial permeability transition is recognized as one important mechanism for cytochrome *c* release and caspase activation. In addition, ER-mitochondrial Ca^{2+} fluxes are modulated by the Bcl-2 protein family, and caspase-mediated cleavage of Ca^{2+} transporters then results in further disruption of ER Ca^{2+} handling, with subsequent mitochondrial Ca^{2+} overload and permeability transition. Ample evidence has documented cross-talk among calpains, caspases, and other protease families, which alters the downstream effects of these families on cellular Ca^{2+} fluxes. Finally, Ca^{2+} -regulated processes are also involved in the ultimate fate of dying cells, their clearing by phagocytes due to Ca^{2+} -dependent exposure of surface recognition molecules and secondary lysis. The latter can be brought about by caspase-dependent cleavage of the plasma

membrane Ca^{2+} ATPase (PMCA), which results in a secondary Ca^{2+} overload and the activation of Ca^{2+} -dependent mechanisms causing cell lysis.

Cell–Matrix Interactions

J A Askari and M J Humphries, University of Manchester, Manchester, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Extracellular matrix (ECM) A network of proteins and polysaccharides underlying and surrounding cells.

Focal adhesions Points of anchorage of the cell to the underlying matrix allowing communication between the inside and outside of the cell via integrins.

Inside-out signaling The modulation of integrin–ligand binding activity by intracellular events, leading to integrin clustering and conformational changes.

Integrins A family of $\alpha\beta$ heterodimeric cell surface receptors for extracellular matrix proteins.

Outside-in signaling The modulation of cell phenotype or behavior by extracellular events such as ligand binding and application of force.

Syndecans A family of transmembrane glycoprotein cell surface receptors for extracellular matrix proteins that can synergize with integrins.

The extracellular matrix (ECM) is a network of macromolecules that underlies all epithelia and endothelia and that surrounds all connective tissue cells. The ECM provides mechanical support and also profoundly influences the behavior and the differentiation state of cells in contact with it. The main receptors mediating the interaction of cells with ECM proteins are known as integrins, referring to their function of integrating the cell's exterior with its interior. Following ligand binding, the cytoplasmic domains of integrins connect to the cytoskeleton and trigger the assembly of signaling complexes. Conversely, the binding of intracellular cytoplasmic components influences cell adhesiveness by altering integrin conformation. Thus, a large variety of complex signaling events can be transduced by integrins in a bidirectional manner across the cell membrane. These events serve to modulate and coordinate many aspects of cell behavior, such as proliferation, survival, shape, polarity, motility, gene expression, and differentiation that are required for fundamental processes such as development, tissue morphogenesis, and wound healing within multicellular organisms. Integrins are also implicated in several disease processes such as inflammation, thrombosis, and cancer metastasis, whereas mutations in integrin genes lead to deficiencies in leukocyte adhesion, myopathy, and blistering skin diseases.

The Extracellular Matrix

Main Components

The ECM components are diverse in composition, but they generally comprise a mixture of fibrillar proteins, polysaccharides, and glycoproteins synthesized, secreted, and organized by neighboring cells. Collagens, fibronectin (FN), and laminins are the principal components involved in cell–matrix interactions; other components, such as vitronectin, thrombospondin, and osteopontin, although less abundant, are also important adhesive molecules.

Over 20 different collagens exist in mammals, but the most abundant exist as helical molecules that assemble into fibrils

and provide tensile strength for many tissues. The ECM also contains a large number of glycoproteins, the best studied of which is FN, a dimeric molecule that also forms insoluble fibrils. The laminins are heterotrimeric glycoproteins that fold into cruciform-shaped molecules and are important components of basement membranes. Fibrinogen and von Willebrand factor are also considered to be matrix proteins because they function as major adhesive molecules in blood, but they can also pass into extravascular fluid and influence cell function.

Adhesive Motifs

Although matrix proteins are large molecules, their major integrin recognition sites are very short peptide motifs of only three to six amino acids. The best known and most widespread of these adhesive motifs is arginine–glycine–aspartic acid (RGD, using the single-letter amino acid nomenclature). This motif was first discovered in 1984 by Pierschbacher and Ruoslahti in the center of FN, but it is also present and functional in vitronectin, von Willebrand factor, and thrombospondin. The crystal structure of the area of FN containing this motif has been solved and shows the tripeptide extending out as a loop from the surface of the protein. Similar short peptide motifs are present in other matrix proteins (see [Table 1](#)). A constant feature of the motifs is the presence of an acidic residue, either aspartic or glutamic acid, which is an absolute requirement for the adhesive activity of the proteins in which they reside. As yet, no corresponding motif has been determined in laminin; however, integrin binding has been localized to distinct regions within the molecule.

In FN, a second region of the molecule, termed the synergy site, has been shown to work in concert with the RGD motif and to enhance integrin-binding affinity. Part of the synergy site is a pentapeptide proline–histidine–serine–arginine–asparagine (PHSRN). Although they probably exist, no synergy sequences have as yet been defined for other matrix proteins.

Integrins

Structure

Integrins are noncovalently linked dimers consisting of an α - and a β -subunit, and the 18 α - and 8 β -subunits that have been identified in humans combine to form 24 different receptors. Integrin homologs are present in organisms ranging from sponges to humans, indicating their central role in metazoan evolution. Integrins possess large extracellular domains, approximately 1200 amino acids in α -subunits and 800 in β -subunits, a transmembrane domain, and short cytoplasmic regions of 50 residues or less. The exception to this rule is the $\beta 4$ -subunit, which has a cytoplasmic domain of over 1000 amino acid residues. In addition, half of all α -subunits contain an extra 200 residue module toward their N-terminus (see Table 2), which has homology with the von Willebrand factor A-domain and is referred to as the α A- or I- (for inserted) domain. Several α A-domains have been crystallized and all adopt a Rossmann fold characterized by central β -sheets surrounded by α -helices. A conserved motif, the metal-ion-dependent adhesion site (MIDAS), which includes the sequence aspartic acid–any residue–serine–any residue–serine (DxSxS), coordinates a divalent metal cation at the top of the domain. The N-terminus of the β -subunit also contains an A-domain with a MIDAS motif. Electron micrographs show the integrin dimer to have a globular head 8–12 nm in diameter that constitutes the ligand-binding domain from which two stalks 2-nm thick and 14–20 nm in length project; the distal regions of these contain hydrophobic sequences representing the transmembrane domains.

Those α -subunits that do not contain A-domains undergo posttranslational cleavage into a light and heavy chain held together by a disulfide bond, the exception being $\alpha 4$, which is cleaved at a more central position to yield fragments of 70 and 80 kDa. In addition, several integrin subunits, $\alpha 3$, $\alpha 6$, $\alpha 7$, $\beta 1$, $\beta 3$, $\beta 4$, and $\beta 5$, are subject to alternative splicing mainly in their cytoplasmic domains, yielding isoforms that are differentially expressed in specific patterns. This splicing serves to

increase the cell–matrix interaction repertoire and hone the temporal and spatial adhesive responses of cells.

The field of integrin research was advanced enormously by the publication of the crystal structure of the extracellular domain of $\alpha V\beta 3$ in 2001 by a group led by Arnaout. This structure shows that the globular head of the integrin is made up of a seven-bladed β -propeller contributed by the α -subunit and the A-domain from the β -subunit, together with an immunoglobulin fold, termed the hybrid domain, made up of polypeptide sequences from either side of the β A-domain. The integrin stalks are folded into three β -sandwich domains in the α -subunit and four epidermal growth factor like repeats in the β -subunit. The β -subunit also has an N-terminal plexin–semaphorin–integrin domain and a novel cystatin-like fold just before the transmembrane region. An arginine residue, R261, in the $\beta 3$ -subunit A-domain extends into the core of the α -subunit propeller, where it is held in place by aromatic residues, and is the main area of subunit association.

Ligand Binding

All interactions between integrins and matrix proteins are dependent on divalent cations, whereas the ligand-binding specificity of integrin molecules is determined by the particular α – β combination. Some matrix proteins (e.g., FN) can bind to several integrins, or, conversely, one integrin can recognize ligands of diverse structure; for example, $\alpha 2\beta 1$ binds to both

laminin and collagen. In general, each integrin has a specific nonredundant function, which is emphasized by the distinct phenotypes of knockout mice.

The integrin dimers can be broadly divided into three families consisting of the $\beta 1$, $\beta 2/\beta 7$, and $\beta 3/\alpha V$ integrins. $\beta 1$ associates with 12 α -subunits and can be further divided into RGD-, collagen-, or laminin-binding and the related $\alpha 4/\alpha 9$ integrins that recognize both matrix and vascular ligands. $\beta 2/\beta 7$ integrins are restricted to leukocytes and mediate cell–cell rather than cell–matrix interactions, although some recognize fibrinogen. The $\beta 3/\alpha V$ family members are all RGD receptors and comprise $\alpha IIb\beta 3$, an important receptor on platelets, and the remaining β -subunits, all of which associate with αV . It is the collagen receptors and the leukocyte-specific integrins that contain α A-domains.

In non- α A-domain-containing integrins, both the α - and β -subunits are required for ligand binding. An integrin–ligand complex crystal structure showed that RGD peptide binds at the α – β interface, with its arginine residue contacting the α -subunit propeller and its aspartate residue helping to coordinate the divalent cation at the MIDAS site via a carboxyl linkage, which, in the presence of ligand, is occupied. Two further cations are present in the ligand-bound structure, one at a site adjacent to the MIDAS (termed ADMIDAS) and the other at a site in close proximity, termed the ligand-induced metal-binding site. Isolated recombinant α A-domains are able to bind peptide and macromolecular ligands with the same affinity as intact dimer. A crystal structure of the A-domain of $\alpha 2$ in complex with a triple-helical collagenous peptide containing the glycine–phenylalanine–hydroxyproline–glycine–glutamic acid–arginine (GFOGER) motif also shows the carboxyl from an acidic residue, in this case glutamate, from the ligand directly completing the coordination sphere of the metal ion in the MIDAS. This explains the absolute requirement for either aspartic or glutamic acid in matrix adhesive proteins and the dependence on divalent cations for integrin–ligand interactions.

Cation Modulation

The binding of ligand to integrin cannot take place without a divalent cation, which directly contacts a carboxyl group from the ligand. However, cations also play an important role in the regulation of integrin affinity. Integrin $\alpha V\beta 3$ contains six cation-binding sites in the unliganded crystal structure and eight in the presence of cyclic RGD peptide, at least three of which are affected by ligand binding. In general, integrin–ligand binding is stimulated by magnesium and manganese ions and inhibited by calcium ions. However, this situation is complicated by the fact that the binding of one cation can affect the binding of another at a different site. In addition, several cation-binding sites within an individual integrin can influence ligand binding. The physiological relevance of cation modulation of integrin affinity has yet to be resolved.

Activation and Signaling

Focal Adhesions

When cells attach and spread on a matrix ligand, there is an initial clustering of integrins in the membrane, followed by an

accumulation of cytoskeletal and signaling molecules into dynamic structures known as focal adhesions or focal contacts. These structures represent the anchor points of the cell where integrins link the cell to both the underlying matrix and the intracellular actin filaments of the cytoskeleton. The contacts appear as dense plaques, often located near the cell periphery, and provide both a scaffold and a means whereby cells can generate traction during migration. More important, focal adhesions also serve as nucleation points for the recruitment of not only structural proteins such as vinculin, talin, and paxillin, but also many signaling and adaptor molecules able to trigger a cascade of phosphorylation events that can activate numerous downstream targets.

Conformational Changes

Many integrins are not constitutively active, and adhesion of cells to matrix proteins needs to be strictly controlled and regulated in response to environmental changes. Integrins exist in at least three states: inactive, active, and ligand bound; the switching of integrins from an inactive to an active state involves conformational changes not only in the ligand-binding pocket, but also across the whole of the extracellular domain and in the cytoplasmic face. Thus, the activation of the ligand-binding domain in the head and the binding of ligand are coupled via long-range conformational changes to signaling events in the cytoplasm. Conversely, intracellular events effect changes in the cytoplasmic domains that are translated in the opposite direction to the integrin head, allowing activation and ligand binding. This bidirectional communication is termed outside-in and inside-out signaling. There is increasing evidence that these signaling responses are additionally modulated by the application of forces on integrins in adherent cells generated by linkages with the ECM and the cytoskeleton.

Cytoplasmic Domains

The short cytoplasmic domains of integrins play a vital role in integrin function because they control the activation states of integrins and are required to maintain integrins in an inactive state. They are also the sites of interaction with, and linkage to, both cytoskeletal and signaling molecules when clustered in focal adhesions. Interactions between the α and β tails occur by a salt bridge and hydrophobic and electrostatic contacts in the α -helical, membrane-proximal region of both domains, and it is likely that this association is lost on integrin activation, allowing the tails to separate and effector molecules to bind. The β -subunit tail is the principal site for binding of cytoplasmic molecules, whereas the α -subunit plays a more regulatory role in controlling activation.

Many proteins are intimately associated with integrins in focal adhesions, but direct interaction with integrin $\beta 1$ and $\beta 3$ cytoplasmic domains has only been proven for the binding of the structural protein talin and the kindlin family of proteins. The sites of interaction are conserved motifs (a membrane-proximal asparagine–proline–any residue–tyrosine (NPXY) for talin and a membrane-distal NxXY for kindlin) in the integrin β tail with a phosphotyrosine-binding-like (PTB) subdomain present in the other molecule. This interaction may be the prototype for other protein interactions with integrin β tails through

PTB domains. While the binding of talin is established as the essential, final common step in integrin activation, it is clear that the kindlins play a major role in regulating this process.

Signaling by Integrins

Integrin-mediated signaling can be broadly divided into two categories, direct and collaborative. In the first, ligation and clustering of integrins are the only stimuli and adhesion to ECM proteins activates cytoplasmic tyrosine kinases, for example, focal adhesion kinase and serine/threonine kinases such as those in the mitogen-activated protein kinase cascade. Direct signaling also induces ionic transients (e.g., Ca^{2+} and Na^+/H^+) and stimulates lipid metabolism. In collaborative signaling, integrin–ECM adhesion modulates signaling initiated by other types of receptors, such as receptor tyrosine kinases and G-protein-coupled receptors, allowing cells to integrate positional information concerning matrix contacts with information about the availability of soluble growth or differentiation factors that are also located in the ECM. An important example of collaborative signaling has been demonstrated between integrins and syndecans, heavily glycosylated proteins that are receptors for ECM proteins as well as soluble growth factors. Most ECM molecules contain binding sites for both integrins and syndecans and there is substantial evidence that a full cell-adhesion response requires engagement of both types of receptor.

Cells that are deprived of anchorage to the ECM eventually die by a specialized form of programmed cell death (apoptosis) known as anoikis. Cell–matrix interactions via

integrins are thus essential for cell survival. Integrins also directly affect the organization of the cytoskeleton, and consequently cell motility, by activating the Rho guanosine triphosphatases (GTPases), a branch of the Ras GTPase superfamily, particularly CDC42, Rac1, and RhoA. Rho promotes the formation and maintenance of actin stress fibers, whereas Rac and CDC42 regulate structures such as lamellipodia and filopodia, respectively.

It is worth remembering that each signaling pathway mentioned influences others at some point, so signaling within a cell is better considered as a series of networks rather than a direct path. Thus, integrins are able to modulate, either directly or indirectly, every signaling pathway within the cell, a fact that emphasizes the importance of cell–matrix interactions on all aspects of cell behavior.

Glossary

Actin filament A filament of ~8 nm in diameter, made up from two helical strands of actin monomers.

Filopodia Bundles of unipolar actin filaments, ~0.2 µm in diameter, that protrude from the cell edge, normally in association with lamellipodia and ruffles. Filopodia and lamellipodia are interconvertible assemblies of actin filaments. Bundles resembling filopodia that do not extend beyond the cell edge are sometimes referred to as 'microspikes'.

Focal adhesions Adhesion foci, longer-lived than focal complexes that link to contractile actin bundles (stress fibers) in the actin cytoskeleton. Both focal complexes and focal adhesions harbor more than 50 proteins, involved in structural and signaling activities.

Focal complex A site of early adhesion to the extracellular matrix, formed beneath a lamellipodium or a filopodium.

Focal complexes either can form and dissolve, within 1–2 min, or can mature into focal adhesions.

Integrins A family of transmembrane receptor molecules that cluster at adhesion foci to link the matrix on the outside to the actin cytoskeleton on the inside.

Lamellipodia Thin, membrane-bound leaflets of cytoplasm, 0.2–0.3 µm thick and up to several microns wide that are protruded at the cell edge, close to and parallel to the substrate. They are composed of unipolar networks of actin filaments.

Rho (Ras homology) proteins A subfamily of small guanosine triphosphatases whose roles include signaling to the actin cytoskeleton.

Ruffles Manifestations of lamellipodia, often including filopodia, protruding upward from the dorsal cell surface, and migrating generally rearwards over it. Ruffles can also occur in dorsal circular arrays, especially in malignant cells.

The morphogenesis of multicellular organisms involves the extensive migration of cells from primordial sites to locations destined for specific tissue development. Among the most dramatic are the movements of cells of the neural crest, which travel from the neural tube to distant sites where they differentiate into diverse cell lineages. The fusion of epithelial layers, such as those which occur during closure of the neural tube, entails coordinated cell migration. In the adult, wound closure and tissue repair depend on the migration of surrounding cells to effect the regeneration process. In defense against foreign organisms, cells of the immune system are mobilized and migrate to the sites of inflammation to engage with the enemy. In another context, cell migration contributes to the dissemination of malignant cells in the spread of cancer. Understanding cell migration has therefore much to do with life and death, which concerns all.

Metazoan cells migrate by a crawling mechanism that entails continuous changes in shape. Crawling, in turn, requires traction and this is provided by the development of transient points of anchorage with the connective tissue scaffold and with other cells. In both processes, shape change and traction, the intracellular polymer framework of the cell, the so-called cytoskeleton, plays a central role. Changes in the cytoskeleton framework are influenced, in turn, by the chemical and mechanical properties of the surrounding matrix, so there is an active crosstalk between the two. Most of what is known about the mechanisms of cell migration comes from studies of cells moving on planar surfaces *in vitro* and from investigations of the test tube properties of cytoskeleton polymers and their associated proteins. However, parallel studies indicate that the basic principles derived from these approaches apply also to cell movement in a tissue environment.

The Cytoskeleton

The cytoskeleton is composed of three distinct, but interlinked networks of polymers, composed of actin, tubulin, and proteins of the intermediate filament family, together with many associated proteins. The term 'cytoskeleton' is a misnomer, because the cytoplasmic filament networks that make it up are in a state of continuous turnover and rearrangement. Cell migration is driven primarily by the programmed turnover of the actin cytoskeleton, but microtubules exert an important influence on polarization and guidance, which is required for directional motility. Intermediate filaments do not appear to play an important role in cell motility, but a subtle modulatory role cannot yet be excluded.

The Actin Cytoskeleton

The actin cytoskeleton is composed of actin filaments organized in networks and bundles: the salient features of the actin cytoskeleton in a fibroblast are illustrated in [Figures 1](#) and [2](#). The cell periphery is delimited either by bundles of actin filaments, running parallel to the cell edge or by dense actin meshworks that are commonly punctuated by small, radial actin bundles, termed filopodia or microspikes (Fp, Ms; [Figures 1](#) and [2](#)). The actin meshworks (Lp, [Figure 3](#)) are the structural component of the sheet-like protrusions at the cell periphery called 'lamellipodia' (or ruffles, when they fold upwards). The body of the cell is pervaded by a loose network of actin filaments, a proportion of which are organized into prominent bundles, called stress fibers (Sf, [Figures 1](#) and [2](#)).

Figure 1 General features of the actin and microtubule cytoskeletons of a migrating cell. Actin filaments are in green, microtubules (Mt) in orange. Protrusion of the cell is driven by the polymerization of actin filaments organized in sheet-like meshworks (lamellipodia, Lp) and bundles (filopodia, Fp; microspikes, Ms). Early adhesions formed beneath protrusions as focal complexes (Fx) can mature into larger, focal adhesions (Fa) connecting the ends of actin bundles, called stress fibers (Sf) via transmembrane receptors to the matrix. Actin filaments in protruding regions are similarly polarized, with their fast-growing +ends directed forwards. Immediately behind the protruding front, in the lamella (La) and the rest of the cell, actin filaments interact in anti-parallel arrays with myosin filaments (blue) to form contractile assemblies, which function in retraction. The polarization of the cell is reflected in a polarization of the adhesion pattern, with stationary focal complexes and focal adhesions at the front and sliding focal adhesions at the rear. Microtubules emanating from the centrosome interact with adhesions and influence their turnover. N, nucleus. Details of the boxed areas are provided in [Figure 4](#). that contain also myosin (My, [Figure 2](#)) to confer contractility. According to cell type, the ratio of peripheral actin meshworks to stress fibers differs and, as a general rule, cells that migrate faster have fewer stress fiber bundles in the body of the cell. The different organizations of actin filaments that make up the subcompartments of the actin cytoskeleton are signaled via pathways involving different members of the Rho family of small guanosine triphosphatases (GTPases): Rho for stress fibers, Rac for lamellipodia, and Cdc42 for filopodia.

One important feature of the actin cytoskeleton is its linkage to the cell membrane, which explains its pivotal influence

on cell form. Major sites of linkage occur at the termini of the stress fiber bundles, which in turn correspond to sites of adhesion of the cell to the extracellular matrix. Because of their focal nature, these sites are called focal adhesions (Fa, [Figure 1](#)). They comprise more than 50 structural, adaptor, and signaling proteins that form and regulate the linkage of the actin cytoskeleton, via transmembrane receptors of the integrin family, to the extracellular matrix (see also [Figure 4\(c\)](#)). The precursors of these anchorage sites are assembled in association with lamellipodia and filopodia at the cell periphery and are called focal complexes (Fx, [Figure 1](#)).

Phases of Movement

In general terms, the mode of translocation of a cell can be divided into three phases: (1) protrusion of a cell front; (2) the development of adhesion to the substrate for the purpose of traction; and (3) retraction of the cell rear.

Protrusion

In the first step of movement, the cell protrudes lamellipodia and filopodia: sheet-like and rod-like processes $\sim 0.2 \mu\text{m}$ thick and several microns in length (Figures 3, 4(a) and 4(b)). The rate of protrusion varies in the range of $\sim 2\text{--}15 \mu\text{m min}^{-1}$. Protrusion is

Figure 3 Electron micrograph of the protruding front of a fibroblast showing the actin filament network in a lamellipodium (Lp) and bundled filaments in filopodia (Fp). Image supplied by Stefan Koestler. Bar = $0.5 \mu\text{m}$. From Small JV and Rottner K (2010) Elementary cellular processes driven by actin assembly: Lamellipodia and filopodia. In: Carrier M-F (ed.) *Actin Based Motility: Cellular, Molecular and Physical Aspects*. Springer Science.

effected by the local nucleation and unidirectional polymerization of actin filaments on the cell membrane. Complexes of proteins including actin nucleation promoting factors and elongation factors are recruited at these membrane sites to signal and drive actin polymerization, downstream from Rac and Cdc42. A subset of these protein complexes collaborates in the formation of actin networks to form lamellipodia and another induces actin bundles to form filopodia (Figures 4(a) and 4(b)). Filaments from lamellipodia can be recruited to form filopodia so there is a mutual interplay, not yet understood, between the different nucleation and elongation factors.

Additional proteins are responsible for cross-linking the formed actin filaments into meshworks (lamellipodia) and bundles (filopodia) and for disassembling the majority of actin filaments at the base of lamellipodia and filopodia to replenish the actin monomer pool (Figure 4). Protrusion therefore involves a regulated treadmilling of actin monomers from the front to the rear of lamellipodia and filopodia. This treadmilling can be experimentally visualized as a retrograde flow by following the recovery of fluorescence after photobleaching of cells expressing actin-green fluorescent protein (GFP) (Figure 5).

Adhesion

In addition to their role in protrusion, lamellipodia and filopodia initiate adhesion to the extracellular matrix. This involves the recognition of matrix ligands on the outside and the accumulation of integrins and proteins of the adhesion machinery to form specific focal points, the focal complexes (Figure 1). The accumulation of proteins in focal complexes is likely linked to the cycling of proteins through lamellipodia and filopodia by retrograde flow.

Figure 4 Schematic view of the actin cytoskeleton at sites of protrusion and adhesion. (a, b) Actin filament organizations in and transitions between lamellipodia (a) and filopodia (b), corresponding to the region in Figure 1 boxed in red. Receptors on the membrane signal down to nucleation promoting factors that dock onto the membrane and initiate actin polymerization. One type of nucleation factor signals the formation of actin networks and another the formation of arrays of parallel actin filaments. Small parallel arrays, likely pairs of filaments stabilized by short actin cross-linkers, cluster to form microspike and filopodia bundles. Further proteins cross-link filaments in the meshwork to form structurally stable arrays. Toward the base of lamellipodia a large proportion of filaments is severed and depolymerized to provide monomer for polymerization at the front. (c) Side view of a focal adhesion, corresponding to the region in Figure 1 boxed in blue. Transmembrane receptors (mainly integrins) couple the matrix on the outside of the cell to actin filaments on the inside via a cohort of structural, adaptor, and signaling proteins. The actin filaments are cross-linked into bundles and interact with myosin to form contractile arrays. Microtubules carrying signaling complexes at their tips interact with adhesion complexes to influence their turnover and thereby the polarity of the cell. Graphic conversions by Tibor Kulcsar. Modified from Nemethova M, Auinger S, and Small JV (2008) Building the actin cytoskeleton: Filopodia contribute to the construction of contractile bundles in the lamella. *Journal of Cell Biology* 180: 1234–1244.

Focal complexes do not move relative to the substrate and can experience one of two fates. They either exist transiently for a few minutes and then disperse or enlarge and differentiate into larger anchorage sites at the ends of stress fiber bundles, the focal adhesions (Figures 1, 4(c), and 6). The transition from focal complexes to focal adhesions is linked to a switch in signaling from Rac/Cdc42 to Rho and to the engagement of muscle-type myosin with actin to form contractile bundles. Filopodia are often involved in focal complex formation and in initiating the assembly of contractile bundles (Figure 6).

The regulation of adhesion formation and turnover is a complex process that involves both enzymatic and mechanosensory pathways. Both focal complexes and focal adhesions are enriched in tyrosine kinases as well as their substrates, and changes in their activities modulate adhesion complex turnover. Focal adhesion formation and maintenance depend also on mechanical stress in the actin cytoskeleton. This is illustrated dramatically by their disappearance when cells are treated with drugs that inhibit the interaction between muscle-type myosin and actin. Mechano-sensory mechanisms therefore play a role in regulating adhesion dynamics, most likely through mechanically induced conformational changes of specific proteins in adhesion sites.

Adhesion Asymmetry and Polarization

For a cell to move, it must develop an advancing front and a retracting tail (Figure 2). This polarization process is reflected in an asymmetry of the pattern of adhesions developed with the extracellular matrix (Figure 6). It is interesting to consider how this asymmetry is established as it is relevant to the question of how polarization is determined.

As long as a cell edge protrudes, focal complexes are created in newly won territory under lamellipodia and filopodia, and a proportion differentiates into focal adhesions. In general, however, lamellipodia and filopodia do not protrude in a persistent manner. Instead, forward advancement is the net result of repetitive protrusion and retraction events. Retraction involves the withdrawal of lamellipodia or filopodia, or their backfolding, as ruffles. When this occurs, focal complexes dissolve, or convert into focal adhesions that temporarily tether the retracted cell edge.

In the above context, polarization can be considered the result of regional changes in the ratio of protrusion and retraction events at the cell edge. Thus, at the advancing front of a migrating cell the duration of protrusion exceeds that of

retraction. Elsewhere, at the rear and flanks, protrusion can occur, but retraction dominates. In the simplest terms, the front edge of a migrating cell is accordingly populated by focal complexes and the rear edge by focal adhesions. In many cases, focal adhesions are also formed behind the front edge and contribute to traction (**Figure 6**). This asymmetry of adhesion site development is the hallmark of a polarized cell. An important difference between focal adhesions at the front and rear of migrating cells is that those at the front remain fixed relative to the substrate, whereas those at the retracting rear and flanks can slide. The anterior adhesions therefore provide anchorage points for the actin cytoskeleton that support the retraction of the trailing cell body. Retraction itself is driven by the interaction of myosin with the actin filaments of the cytoplasmic network (**Figures 1 and 2**).

Microtubules and Cell Guidance

When fibroblasts are treated with drugs that disassemble microtubules, they become depolarized and extend protrusions in all directions. At the same time, tension in the actin cytoskeleton increases and focal adhesions grow in size. These changes are linked to an increase in the activity of Rho. Microtubules are therefore required for polarization and they exert their influence on polarity via a cross-talk with the actin cytoskeleton. The cross-talk apparently takes place between the tips of microtubules and the focal adhesion sites at the ends of actin bundles (**Figures 1 and 4(c)**).

Microtubules grow from the centrosome toward the cell periphery, but not in a continuous manner. Instead, they exhibit alternating periods of polymerization and depolymerization regulated by some of a growing number of proteins that accumulate at microtubule tips. When they reach the cell periphery, microtubules target focal adhesions and this targeting can occur in a repetitive manner. Targeting is more frequent at retracting cell edges and is correlated with the dispersal of focal adhesions or with their release from the substrate.

The global effect of microtubules is to reduce cell contractility. At the level of focal adhesions, microtubules appear to mediate the localized relaxation of actomyosin interactions

at the ends of stress fibers, to promote focal adhesion disassembly. This occurs in a mechano-sensory feedback mode, whereby an increase in mechanical stress at adhesion sites signals the polymerization of microtubules into them. The dependence of a cell on microtubules to maintain polarity is linked to the extent of formation of focal adhesions. Very motile cells, such as neutrophils, do not form stress fibers and typical focal adhesions and are less dependent on microtubules for directional locomotion. Likewise, fish epidermal keratocytes exhibit focal complexes, but lack focal adhesions and can also migrate without microtubules. Some cells appear to have the inherent ability to segregate protruding and contractile domains. However, most cells are unable to maintain this segregation without the modulatory input of microtubules. The nature of the putative molecular cross-talk between microtubules and adhesion sites, likely involving microtubule tip proteins, remains to be clarified.

Actin Filament Recycling: From Protrusion to Retraction

In their role as protruding organelles, lamellipodia and filopodia are major sites of actin filament generation in a motile cell. Whereas a proportion of the filaments generated for protrusion is depolymerized at the base of lamellipodia and filopodia, some filaments survive to seed formation of the rest of the actin cytoskeleton behind, which later serves in retraction. An important feature of this process is the conversion of filaments organized in polarized arrays for protrusion, into arrays of filaments organized in antiparallel arrays, for collaboration with myosin in contraction (**Figures 1 and 2**). The conversion from parallel to antiparallel arrays results from the active contralateral and rearward movements of filopodia and from the folding backward of some lamellipodia and filopodia into the cell as ruffles (**Figure 7**). In addition, those filopodia active in adhesion formation relinquish their basal parts to initiate the formation of contractile, stress fiber bundles. This recycling activity occurs around the entire cell periphery, to a more or lesser extent. The direction of movement is then determined by the region of the cell with the upper hand in protrusion, namely where lamellipodia and filopodia dominate (**Figure 7**).

Figure 7 Actin filament re-cycling, from protrusion to retraction. Schematic illustration of the generation of contractile arrays in a hypothetical cell lacking stress fiber bundles (e.g., a neutrophil). Ruffles, including lamellipodia and filopodia, fold back into the cell and contribute actin filament seeds for the formation of antiparallel assemblies with myosin that interconnect throughout the cell body. The bilateral flow of filaments in lamellipodia also contributes antiparallel filament arrays via the base of the lamellipodium. The contractile bundle around the periphery of the trailing part of the cell is formed via prior ruffling activity at those locations. Actin filaments are in green, myosin filaments in blue. Modified from Small JV and Rottner K (2010) *Elementary cellular processes driven by actin assembly: Lamellipodia and filopodia*. In: Carrier M-F (ed.) *Actin Based Motility: Cellular, Molecular and Physical Aspects*. Springer Science.

Migration *In Vivo*

Cells migrating in tissues exhibit both filopodia and lamellipodia. These thin protrusive extensions are ideal for exploring and penetrating tissue spaces. They are also well suited for intercalating between cells, such as during the migration of leukocytes across endothelial layers. Stress fibers, as seen in cultured cells, are not obvious features of cells moving in a three-dimensional environment. However, inhibition of the Rho pathway – which signals contractility – inhibits the migration of primordial cells during embryogenesis and prevents tail retraction during the transendothelial migration of monocytes. Migration *in vivo* therefore involves protrusion of lamellipodia and filopodia signaled by Rac and Cdc42 as well as retraction signaled by Rho. The closure of epithelial layers during embryogenesis is likewise dependent on protrusion and retraction events, whereby the contractility of actin bundles parallel to the epithelial boundary contributes to closure in a zipper-like mode.

Further factors important for cell migration have not been discussed here. These include the cues initiating migration at an appropriate timepoint and the gradients of chemotactic factors that define the destinations of migrating cells. Needless to say, these must impinge on the network of pathways that signal to the locomotion machinery.

Glossary

Adaptor protein A signaling protein that has no intrinsic catalytic activity but serves as a scaffold to activate other proteins or bring signaling proteins together.

Basement membrane A specialized, thin (~0.2- μ m-thick) extracellular matrix (ECM) that is found at the basal surface of epithelial cell sheets, composed of collagen IV, laminins, proteoglycans, entactin, and other glycoproteins.

Cell adhesion The process by which a cell attaches to the ECM using specific cell-surface receptors, including integrins and proteoglycans.

Cell-cell adhesion The process of cell attachment to other cells, usually through cadherins, cell-adhesion molecules (CAMs), and integrins.

Cell migration The process by which a cell moves from one location to another, involving membrane protrusion, cell adhesion, and forward translocation of the cell body.

Collagen The major structural protein of vertebrates and comprising a family of over 18 types of collagen that are fibrillar and nonfibrillar.

Extracellular matrix The proteins, proteoglycans, and carbohydrates that comprise the environment and connective tissue surrounding cells.

Fibronectin A specific ECM glycoprotein deposited largely by fibroblasts and containing several binding sites for cellular receptors, collagens, and proteoglycans.

Focal adhesions The site where integrin and proteoglycan receptors are clustered and connect to the ECM on the outside of the cell and the actin cytoskeleton on the inside of the cell; focal adhesions are additionally the site where over 100 signaling molecules are scaffolded in response to cell adhesion.

Glycoproteins Extracellular proteins that contain sugar moieties covalently attached.

Integrins The major class of cell-adhesion receptors for the ECM, integrins, are obligate heterodimers comprised of an α - and a β -subunit that can combine to result in ligand specificity for the ECM.

Invasion The process by which cells migrate into tissues and three-dimensional (3D) matrices, which involves the steps of cell migration, and may include proteolysis of the ECM.

Microenvironment The conditions, including ECM, growth factors, pH, glucose, oxygen, and other components that are proximal to cells.

Proteases Proteins that have enzymatic function to cleave other proteins.

Proteoglycans A family of molecules comprised of a protein core and covalently linked glycosaminoglycan side chains.

Rho GTP-binding proteins A subfamily of small guanosine triphosphate (GTP)-binding proteins within the Ras superfamily comprised of Rac isoforms, Rho isoforms, and Cdc42; small GTP-binding proteins cycle between an inactive, GDP-bound form, and an active, GTP-bound form; activation is accompanied by a conformational change that allows the protein to bind to and activate down-stream effector molecules.

SH2 domains A specialized protein domain that can bind to phosphorylated tyrosines when they are in a Y-x-x-P motif (tyrosine-any peptide-any peptide-proline).

Tyrosine kinase A signaling protein that has catalytic activity allowing it to add a phosphate group from the γ phosphate of adenosine triphosphate (ATP) to a tyrosine residue of a protein; usually the tyrosine residue occurs in a particular context, and not all tyrosines are substrates for a particular tyrosine kinase.

Introduction

For a few decades, biologists have studied cell migration in the hopes of better understanding this complex event. Much of the work has been performed in cell culture environments, often on a two-dimensional (2D) plastic or glass surface coated with proteins. The study of cell migration in 2D has allowed the simplification of conditions to better understand the contributions of the extracellular matrix (ECM), cell-surface receptors, and signaling pathways that are involved. The relative ease of imaging a mostly flat cell crawling along a 2D surface has allowed detailed dynamic analysis of adhesion structures and the associated cytoskeleton at various stages of cell migration. From this seminal body of work, much understanding has emerged regarding the dynamics of cell migration, and we now appreciate that cell migration in 2D involves several

steps: forward protrusion of the membrane driven in part by dynamic polymerization and de-polymerization of both actin and tubulin-based cytoskeletal structures, formation of early or nascent adhesions to the underlying substratum, forward translocation of the cell body, strengthening of adhesions at the front, and weakening or tearing of adhesions at the rear to pull forward the rear of the cell (Figure 1).

Using this knowledge as a base, the field of cell migration is now ready to tackle the more complex questions of how cells migrate within 3D matrices, which is necessary in order to understand cell migration *in vivo*. There are several examples of cell migrations during both normal development and pathological conditions to which this knowledge is relevant. This article focuses specifically on our current understanding of cell migration and invasion within 3D matrices, both in culture and *in vivo*.

Figure 1 Stages in cell migration. Cells adhere to the ECM using integrin receptors and quickly reorganize their actin to initiate cell spreading. Cells migrate with a forward thrust of the leading edge, which involves the polymerization of actin into a branching network. This allows the cell to contact the ECM at this protrusion. Cell adhesions start out small and dynamic at the leading edge, and over time mature as more proteins are clustered into the adhesions. This stabilizes the front of the cells. At the rear of the cell, contractile forces move the cell forward and result in release or tearing of the rear adhesions, and forward translocation of the cell body. Inset: A Cos-7 cell stained to reveal the dense actin network at the leading edge (actin is stained red and appears yellow in this figure where it co-localizes with the signaling molecule, R-Ras).

Structure and Function of the ECM

Cell Migration and Invasion Occurs within the ECM

ECM is a term applied to the collection of glycoproteins and proteoglycans (PGs) that are secreted by cells and deposited into the extracellular spaces surrounding cells. The ECM can be a few proteins surrounding a cell, as part of the cells' microenvironment, or it can encompass several hundred microns or even centimeters of structure that we term connective tissue. Although specialized ECMs exist in specific tissues such as brain, heart, nerves, blood vessels, bone, and cartilage, we can generalize our consideration of the organization and structure of ECM by discussing epithelial organs, as the concepts are similar and relevant to other organ sites.

Epithelial cells sit on a specialized ECM that is a mere 0.2 μm thick, termed the basement membrane (Figure 2). Collagen IV, laminins, PGs, and entactin are major components of this structure and form a densely woven mesh that serves both a biochemical (as a ligand to adhesion receptors) relationship and a structural (restraining) function to the gland. Epithelial cells attach directly to the basement membrane via adhesion receptors found at hemidesmosomes. A similar structure that is laminin rich surrounds individual nerve cells and bundles, and underlies endothelial cells in blood vessels. Thus, basement membranes serve to delineate specialized cells from the surrounding loose stromal connective tissue in multicellular organisms. Such a structure is found in invertebrates such as worms and insects all the way through insects and all vertebrate organisms, demonstrating its important role in the development and maintenance of tissue architecture. Indeed, disruption of the basement membrane is a hallmark of invasive cancer, a process that involves a loss of differentiation.

Surrounding the basement membrane is the stromal matrix, composed largely of collagen I and, to a lesser extent, other fibrillar collagens such as collagen III, as well as fibronectin and PGs. The stromal matrix is loosely organized around epithelial cells, yet also serves both biochemical and structural roles (Figure 2). A similar stromal matrix surrounds nerves, muscle, and blood vessels, although it should be noted that as our understanding of ECM increases, so does our realization that subtle tissue-specific differences exist. Fibroblasts found in the stroma are the predominant source of ECM proteins, although other cell types including macrophages can also deposit ECM. Moreover, in culture, epithelial cells deposit ECM proteins, especially those found in the basement membrane, suggesting they may contribute to this structure.

The ECM Has Both Biochemical and Mechanical Properties

The components of the ECM have long been studied as true biochemical ligands for cell-surface receptors, including integrins and PGs. The ECM exhibits multiple and discrete binding sites within the proteins that compose it. For example, fibronectin has several such sites, including an arginyl-glycine-aspartate-serine (RGDS) site that binds to several integrins, heparin-binding sites, and binding sites within the N-terminus. The RGD sequence has been found in several other ECM proteins, including vitronectin, fibrinogen, and denatured collagen. In addition to sites important for cell adhesion, fibronectin has sites that help cells assemble it into a fibrillar matrix at its N-terminus, as well as sites that bind other ECM molecules such as collagen. A similar story is found for laminins, which have both integrin-binding sites, such as the YIGSR peptide, and heparin-binding sites.

It has recently been suggested that the mechanical and structural properties of the ECM contribute to its tissue

Figure 2 Cells interact with a basement membrane. Epithelial cells organized into the terminal functional unit of a duct, the ascinus, are diagrammed in cross section. Cells attach to the 0.2- μ m-thick basement membrane through integrins at hemidesmosomes and to one another at cell–cell adhesions. Surrounding the basement membrane is the stromal matrix, comprised of collagens, fibronectins, and PGs. Image: a scanning electron micrograph (SEM) image of a mouse mammary ascinus demonstrating collagen fibers wrapped around the ascinus. Collagen fibers appear as ropes of various sizes, depending on the number of fibrils in the bundle. SEM courtesy of Dr. Paolo Provenzano.

specificity and the resulting cellular response. Matrices that have identical composition can vary in stiffness, or elastic modulus. Matrix stiffness can result due to cross-linking of proteins within the matrix, deposition of more proteins, or rearrangement of components. Collagen fibers in particular contribute to matrix stiffness, as an increase in the number of fibers or their cross-linking or bundling results in matrices that are stiffer. The idea that collagen fibers contribute a mechanical constraint on cells becomes intuitive when looking at the scanning electron micrograph in **Figure 2**.

Matrix stiffness can also determine the fate of developing cells. Mesenchymal stem cells that are cultured on stiff matrices that mimic the elastic modulus found in bone differentiate into osteocytes. When the same cells are cultured on an identical matrix differing only in stiffness, softer matrices that mimic muscle stiffness induced cells to become myocytes.

Matrix stiffness is also important in the progression of lung fibrosis in asthma and chronic pulmonary disease, as deposition of collagen and other ECM components causes the lung to become stiffer, aggravating inflammation and diminishing the capacity of the alveoli to expand during breathing. A similar situation is observed in atherosclerosis, where increased deposition of ECM around blood vessels makes the vessels stiffer, resulting in ‘hardening of the arteries’ and an increase in blood pressure as the vasculature loses its elasticity. In atherosclerotic plaques, smooth muscle cells that have infiltrated into the inside of the blood vessel deposit collagen, which forms a stiff nodule. This collagen deposition works in a feed-forward mechanism to promote the proliferation of smooth muscle cells, resulting in an ever-growing plaque that will ultimately occlude a blood vessel.

Interestingly, matrix stiffness accompanies cancer progression as well. A well-known pathological finding in many

cancers is the deposition of ECM, predominantly collagens, around tumors, a process termed desmoplasia. Desmoplasia is associated with poor outcome, and recently several groups have demonstrated that stiff matrices can promote cell proliferation and cancer progression. This finding is consistent with the observation that many tumors can be found by palpation because they are stiffer than the surrounding tissue.

Receptors for the ECM: Integrins

Cell migration will only occur if the cells can attach to the ECM, and thus it is important to consider the adhesive receptors employed by cells for this purpose. The integrin family of cell-adhesion receptors is crucial for cell migration, as blocking these receptors blocks cell adhesion and migration. Integrins are composed of an α - and β -subunit, which can associate in a combinatorial manner to create several receptors (**Figure 3**). The subfamilies are based on the β -subunit, with β 1-integrins being receptors for ECM proteins, including collagen, fibronectin, laminin, vitronectin, tenascin, and other extracellular glycoproteins.

The β 2-integrins are found on hematopoietic cells and mediate leukocyte trafficking out of blood vessels and cell–cell interactions. The β 3-integrins are most important for the unique member, α IIb β 3, which is found only on platelets and mediates platelet aggregation by binding to fibrinogen/fibrin. The α v-subunit is the most promiscuous of the α -subunits, combining with β 1, β 3, β 7, β 8 and predominantly mediating adhesion to vitronectin. The β 4-integrin subunit is unique as it harbors an unusually long cytoplasmic domain that is thought to have additional signaling function. When combined with the α 6-subunit, the α 6 β 4-integrin binds to laminin in the

Figure 3 The integrin family of receptors is composed of an $\alpha\beta$ -heterodimer. These heterodimers are assembled in a combinatorial fashion that determines their ligand specificity and intracellular signaling events. The RGD-binding integrins will bind to exposed arg–glu–asp (RGD) peptide sequences in several molecules, including fibronectin, vitronectin, denatured collagen, and fibrinogen. Adapted from Hynes RO (2002) Integrins: Bidirectional, allosteric signaling machines. *Cell* 110: 673–687.

Figure 4 Signaling pathways associated with matrix adhesions. Integrins are clustered as a result of opposing forces due to contraction of the actin cytoskeleton and the opposing stiffness of the ECM. Contractility is driven by the Rho GTP-binding protein, and its effector, Rho-kinase (ROCK), which in turn regulates MLC phosphorylation, leading to myosin contraction of actin. Clustering assembles numerous signaling molecules, including focal adhesion kinase (FAK) and Src. In turn, the Ras pathway is activated, activating extracellular regulated kinase (ERK), which will translocate into the nucleus and regulate gene expression. ERK can also regulate MLC-kinase (MLCK) and thus impinges upon contractility. Adapted from Provenzano PP, Inman DR, Eliceiri KW, and Keely PJ (2009) Matrix density-induced mechanoregulation of breast cell phenotype, signaling and gene expression through a FAK-ERK linkage. *Oncogene* 28: 4326–4343.

basement membrane and is found in unique adhesion structures, termed hemidesmosomes, at the basal surface of epithelial cells. Upon loss of adhesion to the basement membrane in cancer progression, $\alpha 6\beta 4$ -integrin is recommissioned to mediate cell migration along laminin fibers.

Integrins mediate signal transduction via binding proteins to their cytoplasmic tails, which are generally rather short. Nonetheless, several proteins have been demonstrated to bind directly to integrins, and include actin-binding and signal-scaffolding proteins such as filamin, talin, and paxillin, signaling proteins such as focal adhesion kinase (FAK),

Src-family kinases and phosphatidylinositol kinases, and signaling adaptors such as p130Cas and Shc. Thus, integrins are well poised to transmit signals from the ECM to the inside of the cell (Figure 4).

Proteoglycans

PGs are generally large molecules composed of a protein core to which are attached several sulfated glycosaminoglycans, such as chondroitin sulfate or heparan sulfate. Several PGs are secreted into the ECM, where they bind to ECM

glycoproteins and modify the organization of the matrix. PGs can also exist on the cell surface as trans-membrane proteins. Cell-surface PGs, including the syndecans (1, 2, 3, 4), and melanoma chondroitin sulfate proteoglycan (MCSP) also bind to the ECM ligands at heparin-binding sites within the ECM. Cell-surface PGs are necessary for proper adhesion structures to be formed and collaborate with integrins to mediate cell migration. It has recently been demonstrated that cell-surface PGs regulate integrin function; for example, syndecan-1 can help to activate $\beta 1$ integrins. Moreover, cell-surface PGs can transduce signals: MCSP activates the small guanosine triphosphate (GTPase), Cdc42, while syndecan-4 binds, through its cytoplasmic tail, to protein kinase C.

Clustering of Receptors into Focal Adhesions

Cell-adhesion receptors cluster into specialized adhesion structures, termed focal adhesions, which connect within the cell to actin stress fibers. Indeed, integrins were named decades ago because they appear to integrate aligned ECM fibers outside the cell with aligned actin fibers inside the cell. Early adhesions that are not yet associated with stress fibers, but rather a network of actin filaments, are termed focal contacts. Evidence suggests that these early adhesions are more dynamic than focal adhesions and that focal contacts often mature into focal adhesions as actin stress fibers are formed. The concept of focal contacts and focal adhesions is one that has been well described for cell adhesion and migration on 2D surfaces *in vitro*, but has been challenged for cells within 3D matrices and *in vivo*. However, solid evidence exists for the formation of an adhesive structure, termed matrix adhesion, that is found in cells resident within 3D matrices. When live cells expressing a fluorescent version of the $\beta 1$ -integrin subunit (GFP- $\beta 1$) are imaged in a 3D collagen matrix, we find that the $\beta 1$ -integrin clusters along the collagen fibers (Figure 5). Thus, in this article we use the terms focal contact and focal adhesion to indicate data obtained in 2D studies, and matrix adhesion to indicate data obtained specifically in 3D.

Signaling Molecules that Regulate Cell Adhesion and Migration

Rho GTP-Binding Proteins

The dynamics and maturation of focal adhesions are regulated in part by small guanosine triphosphate (GTP)-binding proteins of the Rho family, Rho, Rac, and Cdc42. These small GTP-binding proteins are members of the Ras superfamily of proteins. As such, they cycle between a guanosine diphosphate (GDP)-bound inactive state and a GTP-bound active state. The active state is accompanied by a conformational change in the protein that allows the GTP-binding protein to bind to other proteins and activate them. These downstream proteins are termed effectors, as they mediate, or effect, the outcome of GTP-binding protein activation. Each small GTP-binding protein can activate several effectors, although exactly which effector is bound under specific conditions is still under investigation.

Both Rac and Cdc42 are found at the leading edge of migrating cells, where they promote membrane protrusion and control the formation of lamellipodia and filopodia by

Figure 5 Integrins cluster at sites of cell adhesion along a collagen fiber. Breast carcinoma cells were engineered to express GFP- $\beta 1$ integrin and cultured within a 3D collagen matrix. Live cells were imaged using multiphoton microscopy to visualize collagen (red, second harmonic generation) and $\beta 1$ integrins (green). Scale = 10 μm . Micrograph courtesy of Kristin Riching.

their regulation of the actin network. This occurs through several effectors that include N-WASP, WAVE, and p21-activated kinase (PAK). Rac and Cdc42 both regulate early focal contact formation and are further activated by cell adhesion. Rho, on the other hand, drives stress fiber formation and maturation of focal adhesions through its effectors, including Rho-kinase (ROCK) and mDia (Figure 6).

Rho is the central player in generating cellular contractility, which is important for cell migration in several ways. Rho signals to ROCK to increase the phosphorylation of myosin light chain (MLC). When phosphorylated, MLC exposes the active site on myosin, engaging its adenosine triphosphatase activity and the subsequent contraction of actin. The bundling of actin into stress fibers and the clustering of integrins into focal adhesions are driven by this actomyosin contractility, initiated by Rho activation. As Rho-generated contractility occurs, the actin cytoskeleton clusters integrins through inside-out signaling, resulting in focal adhesion or focal contact formation.

In 3D matrices, the outcome becomes a bit more complicated. Focal adhesion-like structures form in 3D matrices, but are smaller and differ in the proteins involved compared to those that form on a 2D glass surface. These adhesions, termed matrix adhesions, are formed only when cells are within a 3D matrix that is stiff enough to resist the contraction of the cell

Figure 6 Signaling pathways linked to small GTP binding proteins involved in cell migration. Small GTP binding proteins cycle from an inactive, GDP-bound, form to an active, GTP-bound form. This is regulated by GDP exchange factors. Cdc42 and Rac activate their effectors, including N-WASP and WAVE, to regulate early events of actin polymerization resulting in filopodial and lamellipodial protrusions. These protrusions allow early adhesions to form at sites of ECM contact. Rho activates several effectors including ROCK and mDia to enhance actin bundling, integrin clustering, and adhesion maturation. This stabilizes the cell, allowing further forward protrusion of the leading edge.

against the matrix. If the matrix is compliant, rather than generating matrix adhesions, the cell will contract the ECM, condensing it around the cell. Increasing the signaling through the Rho pathway therefore allows cells to tune their response and contract a stiffer matrix.

The result of this in terms of cell migration is twofold. For cells that find themselves in a stiff matrix, cellular contraction allows the cell to pull against the matrix and move within it. In contrast, within a compliant matrix, such as one that is not organized, cellular contractility allows cells to exert forces on collagen and fibronectin fibers.

Focal Adhesion Proteins

Several proteins are recruited to focal complexes and focal adhesions upon clustering, and serve to transduce downstream signals that regulate the behavior of the cell. A central player is FAK, a tyrosine kinase that auto-phosphorylates itself at Y379 upon clustering (Figure 4). The resulting addition of a phosphate group to Y397 results in a docking site for other signaling molecules that contain SH2 domains, including Src, Grb7, and phosphoinositide-3-kinase. Importantly, all of these molecules that bind to FAK promote cell migration.

The Src tyrosine kinase in turn phosphorylates FAK on Y925 to provide an additional docking site for the adaptor, Grb2. The SHC and Grb2 adaptors are important scaffolds that lead to activation of the Ras GTP-binding protein through its exchange factor, SOS (Figure 4). Ras activation is associated

with cell proliferation, cell survival, and increased cell migration, all properties of tumor cells.

FAK and Src also serve to scaffold the adaptor protein, p130Cas. This molecule, like other scaffolding molecules, has no intrinsic enzymatic function but serves to activate other molecules through binding. In the case of p130Cas, it subsequently binds Crk and the Rac exchange factor DOCK 180/ELMO. Activation of this pathway will thus lead to activation of the Rac GTP-binding protein (Figure 6).

Cell Migration *In Vivo* Has Both Normal and Pathological Outcomes

Cell Migration Is Key to Proper Development

One of the first major events dependent on cell migration occurs early in development during gastrulation, in which invagination and migration of the presumptive ectoderm toward the center of the embryo forms the three layers of the embryo: ectoderm, mesoderm, and endoderm. This process does not occur in embryos lacking fibronectin, indicating the importance of the ECM (and cell migration) during development. As development proceeds, more precise migration events are important, as movement of various cell groups sets up the architecture and specialization of the embryo. Invagination of epithelial sheets via collective cell migration forms glandular organs such as salivary glands and breast from ectoderm, and liver and pancreas from endoderm.

During development of branching glandular organs, such as the lung, breast, and salivary gland, fibronectin becomes deposited along the developing gland at locations where branches are to occur. As the gland develops, it must invade into the surrounding fat pad, and it is therefore of interest to note that collagen fibers are found at these tips, radiating outward in the direction the gland will grow. It is thus postulated that collagen fibers represent a path for the growing end buds to follow as the gland is growing.

The ECM guides cell migration in the peripheral nervous system as well. The peripheral nervous system is derived by migration of neural crest cells from their location ventral and proximal to the neural tube – at the crest of the neural tube – into various locations throughout the body. Once resident in their intended location, peripheral neurons then undergo a specialized form of cell migration in which the neuronal cell body does not move, and long cell extensions, termed neurites, migrate into the target organ(s) and into the central nervous system. Laminin is located along paths on which neurites migrate, and neural crest cells find their way along collagen and fibronectin matrices.

Cell Migration in Immune Trafficking and Wound Healing

Immune cells rely on cell migration throughout adulthood in order to traffic between the blood stream and into tissues to maintain immune surveillance. For example, neutrophils and macrophages are involved in inflammation and wound healing, and readily move out of the blood stream to migrate through tissues toward inflamed or wound sites. These cells are able to recognize chemical mediators, including chemokines released at the wound site to migrate directionally toward the wound, a process termed chemotaxis.

The presence of a wound and its resultant blood clot activates local fibroblasts, which migrate into the wound and deposit a provisional ECM. The provisional matrix in turn allows epithelial cells at the wound site to migrate and close the wound, restoring tissue integrity.

Cell Migration during Pathological Conditions

While wound healing is a necessary process for complex organisms, sometimes this process becomes mis-regulated and pathologic inflammation results. Excess activation and infiltration of immune cells into the lungs of asthma patients is one such example. Many diseases are now thought to either involve directly or are made worse by inflammation, including Alzheimer's dementia, coronary artery diseases, diabetes, and cancer.

Atherosclerotic plaques are characterized by the infiltration of smooth muscle cells, which migrate from their location surrounding arterioles into the lumen of the blood vessel, a location where they are not normally found. These smooth muscle cells exacerbate the plaque by depositing the ECM protein collagen, which recruits yet more smooth muscle cells and possibly immune cells. Rupture of the plaque exposes this deposited collagen, causing platelets to attach to the newly exposed collagen and form a clot. This process activates the platelets to secrete many chemical signals that attract additional cells, which then migrate into the area.

Cell migration in 3D matrices is particularly important in cancer progression. Local invasion into the surrounding ECM is one of the hallmarks of a malignant tumor compared to one that is considered benign. In addition to local spread, as tumors progress they spread to more distant organs, a process termed metastasis. Metastasis is a multistep process that includes local invasion away from the tumor through the surrounding stromal ECM (Figure 7), migration into either lymph or blood vessels (intravasation), flow and trafficking through the blood stream, exit from the lymph or blood vessel (extravasation), and survival and growth in the target organ.

Cancer Invasion Is Facilitated by the Structure of Stromal Matrices

Once formed, epithelial cells normally reside within the confines of the basement membrane. However, transformation of cells to a cancerous state fundamentally alters their relationship to the ECM, such that cancer cells both cross the basement membrane and transit into and through the stromal matrix. It is generally believed that protease activity is necessary for cells to cross the dense meshwork of the basement membrane.

A dynamic feedback relationship exists between a developing tumor and the stromal matrix. As tumors arise and progress, they secrete several cytokines and growth factors that recruit both stromal fibroblasts as well as bone marrow-derived inflammatory cells including macrophages. Intriguingly, the fibroblasts that surround a developing tumor are fundamentally different in their gene expression and behavior than normal resident stromal fibroblasts, and are termed carcinoma-associated fibroblasts (CAFs). When co-cultured with normal cells, these CAFs can make normal cells behave like cancer cells such that the normal cells become invasive and proliferative.

The infiltration and proliferation of cells in the stroma, predominantly CAFs and macrophages, result in an increase in matrix deposition. What is particularly intriguing is that not only do fibroblasts and macrophages step up their production of collagen and fibronectin, but it has recently been shown that they can deposit these fibers as an aligned matrix. During breast carcinoma progression in both animal models and humans, changes in the organization of collagen from a loose ECM to straight and ultimately aligned collagen is a marker of tumor progression (Figure 7).

The production of an aligned matrix is significant, as cell migration *in vitro* is enhanced along 3D matrices that have aligned collagen fibers compared to matrices that are randomly organized. Moreover, the orientation of the collagen is important, such that cells prefer to migrate along fibers that are oriented perpendicular to the tumor boundary, providing a surface akin to a highway on which to migrate. In contrast, when fibers are oriented tangential to the tumor boundary, cell migration is minimal. *In vivo*, cells have been shown to migrate from tumors along collagen fibers, appearing almost tight-rope walkers across the stroma. The finding that perpendicular, aligned collagen forms a preferred substratum for 3D cell migration, and the observation of tumor cells *in vivo* using collagen fibers for migration, suggests that the alteration in collagen alignment that surrounds tumors is a key contributor to local invasion.

Figure 7 Carcinoma cells invade along collagen fibers. (a) Collagen alignment is changed during tumor progression. We have defined tumor-associated collagen signatures (TACSs) that describe these changes. TACS-2: Alignment of collagen fibers tangential to the tumor boundary; TACS-3: Alignment of collagen fibers perpendicular to the tumor boundary. Images are of collagen in mouse mammary tumors (collagen appears white, imaged by SHG). The tumor cells are not visible, but reside in the dark space. The tumor/stromal boundary is drawn in yellow. The cartoon depicts the relationship of the tumor cells to the collagen fibers. (b) Breast carcinoma cells cultured in an aligned collagen matrix align themselves relative to this matrix. Arrow indicates axis of collagen alignment. Cell (yellow) and collagen (green, imaged by SHG). Image courtesy of Dr. Steve Trier. (c) Breast carcinoma cells invade through the collagen-rich stroma in a mouse mammary tumor. Cells were unstained, imaged in a tumor explants. Note the numerous cells migrating in parallel along collagen fibers, which are aligned and guide the cells. Scale = 10 μm . Image courtesy of David Inman.

Migration along aligned collagen fibers may reflect a local density in the presentation of the cell-binding sites along the fibers. It has been observed that cells crawl toward increased density of immobilized ligands, a process termed haptotaxis. Alternatively, or in addition, migration along aligned fibers may reflect an advantage in the mechanics of these fibers, which are likely stiffer along the axis of alignment. Indeed, cells have been demonstrated to choose stiffer substrata for migration in 2D studies, a process termed durotaxis. As an analogy, picture a rope strung between two points, attached at both ends and a bit taut. If you stand at one attachment point and pull the rope along the axis, you will not readily be able to deflect it, and instead the rope will feel stiff. In contrast, if you stand to the side and pull the rope cross-wise from the axis, less force is required to deflect the rope, and it will feel more compliant. Thus, one can envision that a cell crawling along aligned fibers has the advantage of a stiff surface against which to generate contraction forces as well as the presentation of ligands laid out before it in a locally dense and near linear manner.

The Role of Proteases in 3D Cell Migration and Invasion

Proteases Degrade the ECM

The ECM is frequently remodeled by the action of cellular proteases. Proteases that act on the ECM include cysteine proteases (cathepsins), serine proteases such as plasmin

and thrombin, and matrix metalloproteinases (MMPs). The MMPs require a conjugated Zn^{2+} ion and include collagenase (MT1-MMP), gelatinases (MMP2 and MMP9), and stromelysins (MMP-3, MMP-10, and MMP-11). MMPs are secreted as inactive zymogens and are activated upon proteolytic cleavage and inactivated by endogenous inhibitors, the most prominent being the tissue inhibitor of metalloproteinases (TIMPs) family (TIMP-1, -2, -3, and -4). Thus, the MMPs are controlled in part by the balance of activators and inhibitors.

While many of these proteases are secreted into the extracellular space, MT1-MMP is particularly interesting because it is a trans-membrane protein and thus is localized to the cell surface. MT1-MMP is found in specialized protrusions that are involved in matrix degradation, called invadopodia. While invadopodia are similar to lamellipodia and filopodia in their actin-based structure, they differ due to the presence of MT1-MMP. In addition, invadopodia can be identified by the presence of cortactin, an actin binding protein that accumulates in invadopodia and may help to localize signaling molecules or stabilize this structure.

There is currently much debate regarding the role of proteases in 3D migration and invasion. *In vivo*, it is thought that proteases are necessary for carcinoma cells to degrade the basement membrane, which is very dense despite being only 0.2 μm thick. Thus, protease activity may represent an obligate first step before carcinoma invasion can occur. Evidence from several labs suggests that once past the basement membrane,

cells can migrate through the collagen and fibronectin-rich stromal matrix in the absence of protease activity, especially if they have aligned collagen on which to migrate.

Proteases Are Required to Form the ECM

Proteases not only have a degradative function, they are also essential for the formation of the ECM. Collagens are secreted as pro-peptides that must have their N-terminal and C-terminal pro-peptides removed by protease activity. Bone morphogenetic protein-1 (BMP-1) is a protease essential for this process. Fibrin-based provisional matrices at the sites of wound healing are a result of thrombin cleavage of fibrinogen, which is soluble in the serum, into fibrin, which is insoluble and forms a clot to achieve hemostasis.

Proteolytic Fragments Are Functional

One of the other aspects to consider is the role of the proteolytic fragments of the ECM. Several ECM molecules, when cleaved, become active peptides that have function. In the lung, which is rich in elastin, elastase cleaves elastin into peptides that are chemotactic for infiltrating neutrophils. In tumors, cleavage of collagen XVIII forms a molecule called endostatin. Endostatin is released into the blood stream and inhibits angiogenesis in distant sites. There is an observation in cancer biology that removal of a primary tumor sometimes results in growth of the metastases. It is postulated that removal of the primary tumor removes the activity of proteases and the release of endostatin, which was controlling angiogenesis to the metastases.

Proteolysis Can Activate Signaling Molecules

In addition to cleaving the ECM outright, proteases can activate growth factors by releasing them from the ECM. For example, transforming growth factor- β (TGF β) is bound into the ECM in a latent form, and becomes active due to cleavage by MMP-9 or other serum proteases such as plasmin. Like the MMPs, plasmin is secreted as an inactive zymogen, plasminogen, and is only able to activate TGF β in a localized manner where it has been activated.

Finally, cell-surface receptors themselves can be activated by proteolytic cleavage. The protease activated receptor (PAR) family (PAR-1, -2, -3, and -4) is activated upon cleavage by proteases: thrombin cleavage of a small extracellular peptide from PAR-1, -3, and -4 will activate downstream intracellular signaling. MMPs are able to activate cell-surface receptors as well, including the epidermal growth factor (EGF) family of receptors. Thus, in considering cell migration within complex extracellular matrices, many levels of regulation and many sources of activation are at play.

Cell-Cell Adhesion

In tissues, cells are in close contact with their neighbors. In epithelial cells, these cell-cell contacts are maintained by E-cadherins: transmembrane receptors that bind homotypically to E-cadherins on neighboring cells (Figure 2). Similar

to focal contacts, E-cadherin receptors link cytoplasmic signaling molecules to the actin cytoskeleton in structures called adherens junctions. Signaling molecules that are involved in adherens junctions include β -catenin, α -catenin, p120 catenin, and Rho. E-Cadherins are important to signal appropriate cell proliferation, and to provide integrity to epithelial tissues. Similar receptors exist on most cells: N-cadherin and N-CAMs (cell-adhesion molecules) mediate neuronal cell-cell attachments, while PE-CAM mediates attachment of endothelial cells. Cadherins are important to maintain the differentiated state and tissue integrity and regulate processes such as cell proliferation, tissue-specific gene expression, and tissue architecture.

An important aspect in carcinoma migration is the loss of E-cadherin adhesion, which allows cells to escape some of the controls on their growth and movement. In fact, inhibition of E-cadherin is often enough to stimulate cell migration. Many growth factors that promote cell migration do so in part by their negative regulation of cell-cell adhesions. Some studies have suggested that the loss of cadherin-mediated adhesions tips the balance in favor of increased cell-matrix adhesion.

Cells also make use of cell-cell attachments to migrate. For example, during development of the nervous system, N-cadherin and N-CAMs facilitate a process called pathfinding, and allow growing neurites to extend along the neurite processes of their predecessors. This process may be co-opted by migrating tumor cells, which frequently start expressing N-cadherin when they lose E-cadherin. The increase in N-cadherin expression is often associated with an increased ability of carcinoma cells to migrate, and may allow carcinoma cells to track along nerves as part of their dissemination.

Collective and Individual Cell Migration

Cells can migrate either as individual cells, or collectively. When cells migrate collectively, many cells follow a lead cell and migrate as single-files, or as sheets of cells that maintain their cell-cell contact. Several aspects of cell migration that have been mentioned in this article regulate whether cells will migrate individually or collectively (Figure 8). Whether cells migrate individually or collectively is thought to be important in how effective they are at invading into tissues and in disseminating to other organs, and may have important implications for cancer metastasis in particular.

Protease activity is one such regulator. Experiments in which protease activity has been either inhibited or augmented demonstrate that cells without protease activity will migrate individually, while the ability to degrade the stromal matrix is needed for collective migration. This is thought to be a simple restraining function of the ECM: if it is not degraded, the cells must squeeze through the openings available, forcing the cells to behave in an amoeboid manner and migrate more individually. An aligned matrix can overcome the need for proteases. When cells track along aligned fibers, they are able to move in single files that do not require protease activity.

Integrin function and cell-cell adhesion regulate individual migration. Rather surprisingly, when β 1-integrin function is blocked, cells do not migrate as a collective group, but rather as individual cells. Regulation of classic cell-cell attachments is also involved. In carcinoma cells, loss of E-cadherin can

Figure 8 Collective migration in chains and sheets. Upper panels: Visualization of collagen fibers (green) by SHG and fluorescently labeled mammary epithelial cells (red). Collagen matrices are aligned (left) or random (right). Bottom panels: View of mammary epithelial cells migrating into an aligned (left) or random (right) collagen gel. Cells are stained to view f-actin (red) and nuclei (blue). Note that cells invade as chains along aligned collagen fibers. If such topographical cue is missing, as in a random collagen matrix, then cells invade as a sheet. Scale = 100 μ m. Image courtesy of Kristin Riching.

stimulate cell migration and releases the cells from the control of a polarized epithelium. However, often carcinoma cells will switch to other cell–cell adhesions such as N-cadherin, which may also regulate collective cell migration.

Summary

Cell migration through complex ECMs is regulated at several levels: intracellular signaling, cell-surface receptors, the composition and organization of the ECM, protease activity, cell–cell adhesions, and the presence of extracellular stimuli such as growth factors. While cell migration is necessary to set up complex tissues during development, and to maintain immune surveillance and repair wounds in adults, this process can go

awry during inflammation and various diseases. In particular, cancer metastasis is an area where cell invasion and migration through tissues is a key component. As our understanding of the complex events that occur during 3D cell migration advances, so too will our ability to regulate these processes.

Glossary

Epigenetic Referring to or describing any heritable influence on chromosome or gene function that is not correlated with, or dependent on, a change in DNA sequence.

Heterochromatin Cytologically defined regions of the genome that contain repetitive DNA (satellite DNA, transposable elements). A defining feature of heterochromatin is the ability to silence gene expression.

Kinetochores The proteinaceous structure on each chromosome that is responsible for chromosomal attachment to and movement along spindle microtubules.

RNA interference A cellular defense mechanism for specific gene silencing that is induced by double-stranded RNAs that are processed into 21–23-nucleotide small interfering RNAs, causing degradation of homologous endogenous messenger RNA.

The centromere is a specialized mixture of DNA and proteins, and ensures chromosome inheritance and genome stability. As a chromosomal locus, the centromere is the minimal DNA or chromatin element that promotes formation of the proteinaceous kinetochore complex and coordinates chromosome movement in mitosis and meiosis. The centromere also synchronizes aspects of chromosome structure, such as heterochromatin formation, sister chromatid cohesion, and chromosome condensation. It is a multidomain locus, recruiting a variety of proteins with distinct functions.

Organization of the Centromere Region

Cytologically, centromeres have been defined by the visible primary constriction on metaphase chromosomes. This chromosomal locus is structurally complex, and contributes to various processes that ensure chromosome stability. The centromere region can be broadly classified into two major domains that encode kinetochore and heterochromatin functions. The kinetochore and heterochromatin are assembled independently, but each is equally important for complete centromere function and for ensuring chromosome and genome stability. The centromere/kinetochore domain comprises both DNA and proteins involved in chromatin assembly and structural aspects of the kinetochore. The heterochromatin domain is located adjacent to, or flanks, centromeric chromatin. Studies in various organisms have shown that heterochromatin is equally important for centromere function and chromosome inheritance as the kinetochore domain.

Kinetochore Domain

At metaphase, the kinetochore, a proteinaceous multidomain structure, is assembled on the outer surface of the centromere, promoting attachment of the chromosome to spindle microtubules and movement during anaphase.

The inner kinetochore

The inner kinetochore is the region most intimately associated with centromeric DNA and/or chromatin. Many structural

proteins that bind centromeric DNA or contribute to specialized chromatin structure are located here (Table 1). The inner kinetochore contains constitutive proteins that serve as the foundation for the kinetochore, often termed the prekinetochore. CENP-A, a centromere-specific histone H3 variant that replaces H3 in centromeric nucleosomes, is located here and serves as an initiatory signal for kinetochore assembly by recruiting other inner and outer kinetochore proteins.

The outer kinetochore

The outer kinetochore region contains primarily microtubule-associated and chromosomal motor proteins that are involved in chromosome congression to the midzone at metaphase or engage spindle microtubules and move chromosomes to spindle poles in anaphase. In addition, the outer kinetochore contains surveillance or checkpoint proteins that monitor kinetochore attachments to the spindle and regulate the transition from metaphase to anaphase.

The central domain

The region spanning the interior of the centromere and connects sister kinetochores comprises the interior central domain. Centromeric DNA-binding proteins are concentrated here, as well as cohesion and condensation proteins and transiently associated proteins (chromosomal passengers) that coordinate chromosome segregation and cytokinesis.

Heterochromatin Domain

Heterochromatin is a cytologically dense material that is typically found at centromeres and telomeres. It mostly consists of repetitive DNA sequences and is relatively gene poor. Its most notable property is its ability to silence euchromatic gene expression. Centromeres in yeast, fruit flies, and mammals are flanked by heterochromatin, indicating that its repetitive composition or dense chromatin structure may represent an important, conserved function in centromere structure and function. Heterochromatin assembly is linked to chromatin regulation, occurring in a pathway that initiates with methylation of histone H3 at amino acid residue lysine 9 in order to

recruit heterochromatin proteins (HPs), such as HP1 (heterochromatin protein 1). Once heterochromatin is established, cohesion and condensation proteins accumulate between sister kinetochores and chromatids. Mutations in HPs or certain histone-modifying enzymes lead to chromosome mis-segregation and mitotic defects, indicating that heterochromatin contributes significantly to chromosome stability and segregation.

Specification of Centromere Identity and Function

The Centromere as DNA

How are the distinct kinetochore and heterochromatin domains assembled at centromeric regions? A well-debated question in centromere biology has been the role of primary DNA sequence in centromere identity and assembly. In a few organisms, specific DNA sequences are required for centromeric protein binding, while in other organisms, centromere-specific DNA sequences have not been found. In addition, epigenetic mechanisms often determine centromere identity. In short, a centromere is established, and it is consistently maintained at a genomic region, but the site of formation is not determined by the underlying sequence itself. Recent studies indicate that RNA also participates in centromere assembly.

Point centromeres

Centromeres in the budding yeast *Saccharomyces cerevisiae* are the best studied and understood. *S. cerevisiae* centromeres are encoded by three distinct DNA elements (CDE I, II, and III) within a 125-bp region (Figure 1). Two elements (CDE I and III) are absolutely conserved and required to recruit centromere and kinetochore proteins. The centromeric histone CENP-A (Cse4p) is recruited to CDE II, the centromeric element that varies in sequence, but not size, from chromosome to chromosome. The small size of budding yeast centromeres as well as the strict reliance on DNA-protein interactions for

assembly have resulted in detailed molecular maps and models of centromere assembly that are lacking in larger eukaryotes.

Regional centromeres

Centromeres in fission yeast, *Schizosaccharomyces pombe*, and in flies, worms, mammals, and plants are monocentric, forming on a limited, specific region of the chromosome (Figure 1). These centromeres are comprised of multiple subunits encoding kilobase- or megabase-sized genomic regions. Unlike in budding yeast, centromeric DNA sequences are not obviously conserved, and centromere identity and assembly depend largely on epigenetic factors.

Schizosaccharomyces pombe

The three centromeres in fission yeast consist of unconserved central core sequences flanked by inverted arrays of inner and outer repeats. Both the central core and portions of the inner repeats are required for establishment and maintenance of centromere function and for recruitment of CENP-A (Cnp1) and other centromeric proteins. The outer repeats are essential for assembly of centric heterochromatin through histone modifications and noncoding RNAs.

Multisubunit centromeres: flies, humans, and plants

Metazoan and plant centromeres are large, often ranging in size from a few hundred kb to 5 Mb. They primarily consist of thousands of copies of satellite DNA, often arranged in tandem (mammals and plants). In flies and plants, these repeats are often interspersed with transposable elements. In humans, *de novo* centromere assembly via artificial chromosomes has been most efficiently achieved when centromeric satellites (alpha-satellite DNA) are introduced into cells. However, not all human alpha-satellite DNAs form centromere *de novo*, indicating that other sequences or factors are required to assemble and maintain human centromeres.

Figure 1 Centromeric structure in various eukaryotes. Schematic diagram of eukaryotic centromeres. The DNA sequence of centromeres differs between species, but the organization of the centromere and the presence of centromere proteins are conserved. Budding yeast (*S. cerevisiae*) centromeres are 125 bp and are composed of three distinct elements, two of which are conserved (I and III). *S. pombe* (fission yeast) centromeres contain a unique central core flanked by inverted inner and outer repeats. *Drosophila* centromeres extend for 200–420 kb and contain repetitive DNA (red boxes) that is interspersed with transposable elements (green lines). Human centromeres consist of tandemly repeated alpha-satellite DNA arranged into higher-order repeats that extend over several megabases.

Holocentric chromosomes

In the nematode *Caenorhabditis elegans*, crayfish, and some insects, the holocentric chromosomes assemble centromeres along their lengths. *C. elegans* centromeres are the best-studied holocentrics. Most of the known eukaryotic centromere and kinetochore proteins have been identified in worms and the order of assembly, with CENP-A (CeCenp-A or HCP-3) at the top of the assembly pathway, are conserved. Proteins are recruited into distinct foci at prophase, but by metaphase, these foci spread evenly into ribbons along the poleward face of the chromosome arms. The distribution of centromere and kinetochore proteins into inner and outer kinetochore regions is conserved in *C. elegans*.

The Centromere as Chromatin

Chromatin is an important regulator of gene expression and compartmentalization of the genome in interphase. Establishment of distinct chromatin domains (kinetochore and heterochromatin) is necessary for complete centromere function; thus, chromatin may be a more important determinant of centromere function than DNA sequence.

Epigenetic centromeres

The simple presence of centromeric DNA in a cell or a chromosome does not necessarily correlate with centromere function. Besides the obvious lack of sequence conservation at eukaryotic centromeres, additional evidence exists to argue the role of underlying DNA sequence in centromere assembly. First, at

normal mammalian centromeres, only a fraction of the arrays actually participates in centromere assembly. In humans, the kinetochore domain typically comprises one-half to two-thirds of the satellite DNA found at eukaryotic centromeres. The remainder of the satellite DNA is involved in forming heterochromatin and cohesion. Second, naturally occurring or engineered dicentric chromosomes that contain two regions of centromeric DNA are stably transmitted in flies and humans only after inactivation of one centromere. Finally, neocentromeres are formed in flies and humans on stable marker chromosomes that completely lack centromeric sequences. None of the neocentromeres share sequence homology and even those that are derived from similar genomic regions assemble centromere, kinetochore, and HPs on different sequences.

Specification by CENP-A

All centromeres are associated with the centromere-specific histone CENP-A. CENP-A is required to recruit all other centromere and kinetochore proteins, with the exception of HP1, making it a strong candidate for a protein that specifies and maintains the site of kinetochore assembly. Unlike replication-dependent histones, CENP-A is dispersed in a semiconservative manner, thus providing the scaffold on which new CENP-A can be loaded and the centromere can be maintained irrespective of the underlying DNA sequence. The organization of centromeric chromatin may further facilitate its maintenance and/or function. In two dimensions, centromeric chromatin in flies and humans contains interspersed subunits of CENP-A and H3 nucleosomes (Figure 2). CENP-A subunits coalesce

Figure 2 Unique organization of centromeric chromatin creates proper structure of the centromere region. In 2D, CENP-A (red circles) and H3 (green circles) nucleosomes within centromeric chromatin are interspersed, forming the foundation of the kinetochore domain, which is flanked by heterochromatic proteins (squares) and cohesion proteins (triangles). In metaphase (3D), the blocks of CENP-A and H3 nucleosomes may be arranged in a spiral, orienting CENP-A nucleosomes to the poleward face of the chromosome, presumably to bi-orient the chromosome and facilitate recruitment and interactions with other kinetochore proteins. H3 nucleosomes are sequestered to the region between sister kinetochores, where heterochromatin and cohesion proteins are recruited. Flanking heterochromatin that is assembled between sister kinetochores may be as important as CENP-A:H3 interspersions for ensuring that CENP-A opposes spindle poles.

to form a three-dimensional (3D) interface that promotes recruitment of additional kinetochore proteins, biorientation of chromatids to opposite spindle poles, and attachments to microtubules. Conversely, the H3 subdomains are oriented toward the interior of the chromosome to establish a platform for recruiting cohesion and condensation proteins. The unique interspersions of CENP-A and H3 nucleosomes is important for centromere function, because depletion of CENP-A by RNA interference (RNAi) or in CENP-A mutants alters the ratio of CENP-A:H3 and leads to chromosome segregation defects and mitotic arrest.

Incorporation of CENP-A into chromatin is temporally regulated by a unique chaperone. It is clear that CENP-A is a crucial component of centromeres and is required to recruit other proteins that are the structural and functional basis of the kinetochore. As such, it must be replaced each cell cycle, as it is semi-conservatively depleted with each round of DNA replication. When and how CENP-A is loaded specifically at centromere regions and how it is replenished or maintained at these sites have been long-standing questions. Recent evidence has

emerged indicating that CENP-A is loaded at a specific time during the cell cycle and by a specific protein. The timing of CENP-A incorporation occurs in late telophase/early G1 in humans and fission yeast and during metaphase/anaphase in *Drosophila*. In humans, the CENP-A chaperone, Holliday junction recognition protein (HJURP) associates with CENP-A and is recruited to centromeres at the same time that CENP-A is deposited in early G1. HJURP directly recognizes the CENP-A targeting domain (CATD), a motif that is required for both proper CENP-A targeting to the centromere and unique structural and functional properties of the CENP-A nucleosome. In budding yeast, Scm3 may actually chaperone CENP-A^{Cse4p} to the location of nucleosome assembly. It is functionally similar to HJURP, although there is less sequence similarity between the two protein families. HJURP or Scm3 proteins have not been identified in *Drosophila*. Instead, CAL1, a newly identified protein, and CENP-C, a constitutive component of the kinetochore that is present in all organisms, have been shown to be essential for loading newly synthesized CENP-A at centromeres during metaphase–anaphase. Although the protein players vary slightly

among organisms, these findings indicate that CENP-A incorporation at eukaryotic centromeres involves coordination of novel and common centromere proteins.

Current model proposes that existing, or old, CENP-A acts as a centromeric flag or beacon to help target new CENP-A. However, other features of centromeric chromatin, such as the presence of H3 nucleosomes interspersed with CENP-A, post-translational modifications of the N-terminal tails of CENP-A or H3 or chromatin environment, may be part of the signal. In human cells, CENP-N specifically recognizes CENP-A nucleosomes and not H3 nucleosome located nearby. It is thought to read and interpret the chromatin landscape at the centromere and communicate to assembly factors that more CENP-A is needed. At the same time, CENP-T and CENP-W, components of the DNA-proximal constitutive centromere-associated network (CCAN), associate with H3-containing nucleosomes within the centromere region. Studies in the fission yeast argue for a role of chromatin environment in centromere formation. In *S. pombe*, heterochromatin marked with H3K9 methylation by Clr4/Suv39 is crucial for recruiting CENP-A^{Cnp1} to neighboring central core sequences and establishing a functional centromere. Neocentromeres, or ectopic centromeres that form *de novo* at noncentromeric sites, are established at telomere and centromere-proximal regions in *S. pombe* and *Candida albicans*. Both of these regions are normally heterochromatic, suggesting that heterochromatin promotes centromere assembly, at least in fungi. It is unclear if heterochromatin has a similar positive impact on CENP-A deposition in larger eukaryotes, or if independent H3 and CENP-A assembly systems coordinate their actions to establish centromeric chromatin.

The Centromere as RNA

One of the most exciting discoveries in the past few years has been the involvement of double-stranded RNA (dsRNA) in specifying chromosomal, and particularly centromere, function. Although originally considered junk DNA, the arrays of repeats that surround active centromeres have been shown to be functionally significant. In particular, noncoding, antiparallel RNAs are transcribed from the outer centromeric repeats in *S. pombe*. These transcripts are typically unstable and are normally processed by RNAi machinery that mediates the formation of heterochromatin. Full-length double-stranded transcripts from the repeats are reduced into small interfering RNAs (siRNAs) by the protein Dicer, a member of the RNA-induced silencing complex (RISC). The siRNAs then initiate methylation of histone H3 at lysine 9 that subsequently recruits HPs. The siRNAs are only required for establishment, but not

maintenance of heterochromatin. However, RNAs appear to be important for centromere assembly as well. In fission yeast, pericentric heterochromatin and the RNAi components necessary to form it are required to establish CENP-A chromatin on neighboring sequences. RNAs produced from CENP-A regions have been identified in plants and are important for structural and functional aspects of CENP-C binding at centromeres. Transcription from an L1 retrotransposon within the CENP-A region of a human neocentromere has been shown to be important for CENP-A assembly and maintenance. Although transcripts originating from alpha-satellite DNA have been identified at endogenous human centromeres, it is unclear if they are required for CENP-A assembly. With recent findings in other organisms supporting a role for RNA in centromere assembly and function, it is tempting to speculate that kinetochore-specific transcripts from human centromeres might initiate *de novo* centromere assembly that is then maintained by retention of CENP-A and/or other proteins through many rounds of replication and division.

Promoter The DNA sequence upstream to the transcription initiation site that directs expression of the gene.

STAT (signal transducers and activators of transcription) Transcription factors originally identified as mediating the transcriptional effects of interferon.

Structure and Regulation

The human *c-fes* gene is located on chromosome 15 at position 15q26.1 and is comprised of 19 exons, the first of which is noncoding. The *c-fes* locus encodes a 93-kDa protein-tyrosine kinase with several distinct structural regions (Figure 1). These include an N-terminal Fes-CIP4 homology-bin-amphiphysin-rvs domain (F-BAR) region made up of Fes-Cdc42-interacting protein 4 (CIP4) homology (FCH) and coiled-coil (CC) domains, an Src homology 2 (SH2) domain, and a C-terminal kinase domain. Absent are an Src homology 3 (SH3) domain and signal sequences for lipid modification, such as the N-terminal myristoylation site associated with c-Src, c-Abl, and other nonreceptor tyrosine kinases. Fes tyrosine kinase activity can be readily demonstrated *in vitro*. However, unlike its transforming viral counterparts, Fes kinase activity is tightly regulated in cells, even upon high-level overexpression. Both the CC and SH2 domains play important roles in kinase regulation.

F-BAR Region

The N-terminal region of Fes is defined by an N-terminal Fes/Fer/CIP4 homology (FCH) domain followed by at least two CC homology motifs. Together, these domains define an F-BAR region, a structural arrangement encoded by at least 21 other human genes. Proteins with F-BAR domains have been shown to regulate membrane curvature and contribute to cellular processes such as endocytosis, exocytosis, and motility. The presence of an F-BAR region in Fes (and its close homolog Fer) is unique among protein-tyrosine kinases.

The FCH domain was originally defined as a region of homology between Fes, Fer, and a binding partner for the Rho guanosine triphosphatase (GTPase), Cdc42 (CIP4). The *c-Fes* FCH domain has been linked to the regulation of microtubule dynamics, as it associates with soluble tubulin dimers and contributes to Fes-induced nucleation of microtubules both *in vitro* and in cells.

One unusual feature of Fes is its ability to form large homotypic oligomers, both *in vitro* and in cells. Computational analysis of the N-terminal region revealed the presence of at least two CC domains; subsequent biological studies demonstrated that the CC regions are essential for Fes oligomerization. In addition, deletion or mutagenesis of the more N-terminal CC domain strongly upregulates the tyrosine kinase and biological activities of Fes in cells, consistent with a crucial role for this domain in negative regulation. Recent

analysis of Fes oligomerization using a live-cell bimolecular fluorescence complementation approach showed that oligomerization is indeed dependent upon the CC domains, but is independent of kinase activity. Thus, the impact of the CCs on the kinase domain is more likely to involve conformational rearrangements within a preformed oligomeric Fes structure.

The N-terminal region of Fes may also contribute to the recruitment of signaling partners. One example is the breakpoint-cluster region protein (Bcr), better known in the context of the Bcr-Abl oncoprotein associated with chronic myelogenous leukemia (CML). Bcr is a multidomain signaling protein with an N-terminal Ser/Thr kinase domain, followed by a central guanine nucleotide exchange region and C-terminal GTPase-activating domain for small GTPases of the Rho family. Bcr is phosphorylated by Fes on a cluster of sites localized to its N-terminal kinase domain. Expression of this Bcr region suppresses Fes-induced neurite outgrowth in rat PC12 cells, suggesting that Bcr may couple Fes to Rho family small GTPases in neuronal cells. Fes also interacts with Bcr-Abl through the Bcr-derived portion of the protein, an interaction that may contribute to the observed suppression of Bcr-Abl oncogenic signaling by Fes.

Yeast two-hybrid screens using the Fes N-terminal CC domain as bait identified Kruppel-associated box-associated protein-1 (KAP-1) as a unique Fes substrate and binding partner. Like Fes, KAP-1 also has a CC domain, and heterologous CC interactions appear to drive the association of Fes with this transcriptional regulator. Fes:KAP-1 complexes and Fes-mediated KAP-1 tyrosine phosphorylation have been observed in myeloid cells, suggesting a possible link between Fes and the regulation of chromatin structure via KAP-1.

SH2 Domain

SH2 domains are signaling modules that mediate protein-protein interactions in tyrosine kinase signal transduction pathways. By binding with high affinity and specificity to short, tyrosine-phosphorylated target sequences, SH2 domains mediate the assembly of multiprotein complexes in response to tyrosine kinase activation. Although the role of SH2 domains in the recruitment of effector proteins to autophosphorylated growth factor receptors is well known, SH2 domains were first identified within the sequences of nonreceptor tyrosine kinases. In fact, the SH2 domain of the Fes-related oncoprotein v-Fps was among the first to be described, where it was shown to be required for full catalytic activity. Later work established that

Figure 1 (a) Primary structure of the c-Fes protein-tyrosine kinase. Fes consists of an N-terminal F-BAR region, a central SH2 domain, and a C-terminal kinase domain. The F-BAR region includes the N-terminal FCH domain involved in interactions with the tubulin cytoskeleton as well as two coiled-coil (CC) oligomerization domains. (b) X-ray crystal structure of the c-Fes SH2-kinase unit. Note the juxtaposition of the SH2 domain (red) and the N-lobe of the kinase domain (blue), which serves to stabilize the active conformation of the kinase (see text). This model was produced using PyMol and PDB coordinates 3BKB.

v-Fps-induced phosphorylation of transformation-related substrates was also dependent upon this noncatalytic domain. More recent studies revealed a similar dual role for the human Fes SH2 domain in the regulation of kinase activity and biological function. Deletion of the SH2 domain greatly reduces Fes kinase activity in terms of both substrate phosphorylation and autophosphorylation *in vitro*. Recent structural analysis of the Fes SH2:kinase unit provides a mechanistic basis for the positive influence of the SH2 domain on kinase activity. In the crystal structure, the SH2 domain makes direct contacts with the small lobe of the kinase domain, holding the critical α C regulatory helix in an active conformation (Figure 1). Interestingly, ligand binding to the SH2 domain stabilizes the SH2:kinase domain interaction, suggesting that SH2-based substrate recruitment and kinase activation are coupled. Given that the N-terminal CC domain is involved in the repression of kinase activity, it is reasonable to speculate that the N-terminal region may allosterically repress SH2:kinase domain interaction as part of the regulatory mechanism. A structure of the full-length, inactive form of Fes is required to fully appreciate the unique mechanism responsible for negative regulation of its kinase activity.

Kinase Domain

The Fes catalytic domain is localized to the C-terminal region of the protein and exhibits structural features typical of other protein-tyrosine kinases. These include a conserved lysine in the adenosine triphosphate (ATP)-binding pocket (Lys590)

and a major site of tyrosine autophosphorylation (Tyr713) which localizes to the activation loop. Mutagenesis of Tyr713 to Phe greatly reduces catalytic activity both *in vitro* and *in vivo*, suggesting that autophosphorylation is required for kinase activation. Substitution of Lys590 with Glu or Arg completely abolishes kinase activity.

Biological Functions

Myeloid Differentiation

Early studies describing Fes expression patterns noted a striking correlation with terminal differentiation of myeloid hematopoietic cells. Fes expression was absent in myeloid leukemia cell lines resistant to differentiation inducers or selected for differentiation resistance, while expression increased following induction of differentiation with a variety of agents. Chicken bone marrow cells infected with Fujinami sarcoma virus, which carries the *fes*-related oncogene, *v-fps*, undergo macrophage differentiation in the absence of macrophage colony-stimulating factor. Similarly, expression of active c-Fes mutants is sufficient to induce differentiation of myeloid leukemia cells along the macrophage lineage. Consistent with these observations, Fes activation is linked to a number of hematopoietic cytokines and growth factors, including interleukin-3 (IL-3), IL-4, granulocyte-macrophage colony-stimulating factor (GM-CSF), erythropoietin, and Kit ligand (stem cell factor). Upstream regulators of Fes activity also include Fc-linked immune receptors found on macrophages and other cells of innate immunity.

Evidence supporting a requirement for Fes in myeloid differentiation comes from protein knockdown experiments. Suppression of Fes in HL-60 promyelocytic leukemia cells using antisense oligonucleotides blocked myeloid differentiation in response to phorbol esters and other chemical inducers. However, targeted disruption of Fes in mice has yielded contradictory findings with respect to its role in hematopoiesis. Homozygous replacement of the murine *fes* alleles with kinase-defective mutants did not show any remarkable effect on hematopoiesis, although signal transducers and activators of transcription (STAT)3 and STAT5A phosphorylation in response to GM-CSF was markedly reduced. By contrast, homozygous deletion of Fes led to a runted appearance, abnormal myeloid proliferation, but increased STAT3 activation in response to GM-CSF and IL-6. One possible explanation for these apparently contradictory results may involve competition of kinase-dead Fes with Jak2 for STAT3, resulting in a lower degree of STAT3 activation. By contrast, the complete absence of Fes protein may result in less competition with Jak2 for STAT3, resulting in enhanced STAT3 phosphorylation.

Angiogenesis

Other evidence supports a role for Fes in the development of the vascular endothelium. Expression of Fes in transgenic mice under the control of a nonspecific SV40 promoter-induced hypervascularity which progressed to multifocal hemangiomas. The Fes transgene used in these experiments was modified to encode an N-terminal myristoylation sequence on its N-terminus; this modification leads to addition of myristate, membrane targeting, and mild activation of kinase activity. Expression of endogenous Fes was also demonstrated in primary human vascular endothelial cells at levels comparable

to those detected in myeloid cells. Consistent with these findings are the observations that Fes is activated by the angiogenic growth factors fibroblast growth factor-2 and angio-pietin-2 in cultured capillary endothelial cells, and that over-expression of Fes is sufficient to induce formation of tube-like structures and chemotaxis in this cell type.

Is Fes an Oncogene or a Tumor Suppressor?

The observations that Fes may contribute to angiogenesis raises the possibility that it may contribute to neo-vascularization, which is essential for solid tumor growth. In this context, Fes may indirectly support tumor formation. Fes may also contribute to oncogenesis by coupling to c-Kit, the receptor tyrosine kinase required for stem cell factor signaling. Activating mutations have been reported within the c-Kit juxtamembrane region, which lead to ligand-independent kinase activation and drug resistance in gastrointestinal stromal tumors and other forms of cancer. Fes has been implicated as a key downstream signaling partner for mutationally activated Kit, suggesting that selective inhibitors of Fes may have antitumor effects in certain situations. Along these lines, small interfering RNA knockdown of Fes expression has been found to suppress the growth of renal carcinoma cell lines, implicating Fes as an oncogenic factor in this cell type as well.

By contrast, Fes-induced differentiation may overcome signals for transformation in certain forms of leukemia. An early demonstration of this phenomenon involved transfer of the *c-fes* gene into the human CML cell line K-562, resulting in growth suppression and differentiation to macrophage-like cells. K-562 cells were established from a CML patient in blast crisis and exhibit no detectable Fes expression; later work demonstrated hypermethylation of the *c-fes* promoter in this cell line was responsible for gene silencing. Because they are CML-derived, K-562 cells exhibit the Philadelphia chromosome translocation and express p210 Bcr-Abl, the oncogenic tyrosine kinase responsible for CML pathogenesis. Thus, the Fes signal for differentiation is dominant to the Bcr-Abl signal for growth and survival. Fes can also suppress Bcr-Abl-induced transformation of murine myeloid leukemia cells to cytokine independence, providing further support for the idea that Fes may delay the progression of CML.

More recent studies suggest an unexpected role for c-Fes as a tumor suppressor in cancers of epithelial origin. Nucleotide sequence analysis of the tyrosine kinome of 182 colorectal cancer cell lines revealed that *c-fes* was one of only seven genes exhibiting consistent cancer-associated kinase domain mutations. Although these mutations were initially predicted to be activating and contribute to tumorigenesis, subsequent studies established that these mutations rendered Fes either catalytically inactive or had no effect on kinase activity. Subsequent work showed that Fes is strongly expressed in normal colonic epithelial cells from both mice and humans. By contrast, Fes expression was reduced or absent in more than two-thirds of primary colon tumor specimens. Similarly, Fes protein expression was significantly reduced or absent in colorectal cancer cell lines. Re-expression of Fes from a retroviral vector suppressed soft-agar colony formation by two colorectal cancer cell lines where endogenous Fes expression is silenced (HT-29 and HCT 116). Taken together, these results suggest

that loss of c-Fes expression is a common finding in colorectal cancer, an observation that fits with a tumor-suppressor function for c-Fes in this tumor site. Indeed, promoter methylation has been demonstrated to play an important role in suppression of Fes expression in both colorectal cancer cell lines and primary tumors. Along similar lines, breast tumor onset has been observed to occur more rapidly in mice targeted with either null or kinase-inactivating *c-fes* mutations, and introduction of a wild-type *c-fes* transgene rescued the kinetics of tumor onset in the *c-fes* null mice.

Downstream Signaling Pathways

Small G Proteins

Ras and other small GTPases are critical signaling intermediates for most protein-tyrosine kinases, and Fes is no exception. Activation of Ras and the related small GTPases, Rac and Cdc42, are required for fibroblast transformation by Fes oncogenes. Dominant-negative mutants of all three small G proteins inhibit fibroblast colony-forming activity by Myr-Fes and v-Fps, and transformation correlates with constitutive activation of both the Erk and Jnk pathways downstream. Interestingly, sustained Erk activation has also been linked to myeloid differentiation of K-562 cells, suggesting that Fes-induced differentiation in these cells may be due in part to activation of the Ras/Erk pathway. Thus, the ultimate biological response (e.g., differentiation vs. transformation) may be dependent upon the cellular context in which the kinase is active.

The activation and termination of small GTPase signaling are regulated by protein factors (guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs), respectively), which link small GTPases with upstream tyrosine kinases, including Fes and its transforming viral homologs. Transformation of fibroblasts by v-Fps has been shown to induce tyrosine phosphorylation of p120 Ras GAP, and similar results have been observed *in vitro* with purified Fes and GAP proteins. Fibroblast transformation by v-Fps also correlates with tyrosine phosphorylation of Shc, an adaptor protein that links tyrosine kinases to the Ras GEF complex, Grb-2/Sos. As mentioned above, endogenous Bcr is also tyrosine-phosphorylated in fibroblasts transformed by v-Fps. Tyrosine phosphorylation of Bcr in v-Fps-transformed cells induces its association with Grb-2/Sos via the Grb-2 SH2 domain. Like Shc, Bcr may serve as an intermediate between Fes and the activation of Ras downstream. In addition, tyrosine phosphorylation of Bcr may modulate either its GEF or GAP activities toward Rac or other Rho-family GTPases.

STAT Signaling

STATs are transcription factors with SH2 domains that are activated by tyrosine phosphorylation, often in response to cytokine and growth factor stimulation. Although kinases of the Jak family are often associated with STAT activation, a growing body of evidence indicates that Fes and other tyrosine kinases also induce STAT activation. For example, STAT3 DNA-binding activity is strongly activated following co-expression with Fes in Sf-9 insect cells, which lack endogenous Jak kinases. In addition, macrophages from mice with targeted inactivating

mutations in both *fes* alleles show blunted STAT3 and STAT5 activation in response to GM-CSF. STAT3 has been implicated in myeloid differentiation, suggesting that Fes may influence differentiation-related gene expression via a STAT3-dependent pathway.

PI3K Pathway

PI3K phosphorylates phosphoinositol lipids at the 3'-OH position, generating second messengers such as phosphatidylinositol-3,4,5-trisphosphate (PIP3). PI3K is a heterodimer consisting of 85-kDa regulatory (p85) and 110-kDa catalytic (p110) subunits, and interacts with tyrosine phosphorylated target proteins through SH2 domains found in the p85 subunit. Several reports have linked Fes to the activation of PI3K signaling. Early work demonstrated elevated PI3K activity in chick embryo fibroblasts transformed by v-Fps as well as other transforming tyrosine kinases. More recently, IL-4 was shown to induce the association of endogenous Fes with PI3K in IL-2-dependent T-cell lines. The SH2 domain of p85 forms a stable complex with Fes, suggesting a possible mechanism for factor-induced complex formation. The PI3K pathway is often associated with survival signaling, and activation of this pathway by Fes may contribute to macrophage survival. Activation of PI3K is also essential to Fes-induced neurite extension in PC12 cells, where it may couple Fes to Rac activation.

Other Substrates

Many of the substrate proteins reported for Fes have been identified using fibroblast transformation as a model system. However, overexpression of Fes in a macrophage cell line, which represents a physiological cellular context, led to the phosphorylation of proteins related to integrin-mediated responses including adhesion and cell-cell contact. Interestingly, phosphorylation of Shc and other proteins associated with mitogenic responses were not observed. A role for Fes in cell adhesion is further suggested by the interaction of the Fes SH2 domain with cortactin, which is also phosphorylated by Fes. These results suggest a mechanism for the localization of Fes with focal adhesions, which has been observed in fibroblasts and in vascular endothelial cells.

Transcriptional Regulation of Fes

Transgenic mice expressing a 13-kb human genomic *c-fes* clone faithfully reproduced the myeloid expression pattern of the endogenous gene, suggesting that the relatively compact 5' untranslated region (UTR) contains a tissue-specific promoter. Myeloid-specific expression has been attributed to a tissue-specific repressor acting at promoter region +441 to +454 (relative to the transcription start site), a Fes-specific transcription factor (*c-Fes* expression factor, FEF) binding to a *cis*-acting element at -9 to -4 and to transcription factors Sp1, PU.1, and Spi-1 binding to elements within the -425 to +75 promoter sequence. Although these studies account for the myeloid-selective expression of Fes, they do not address Fes expression in other tissues, such as vascular endothelial and gut

epithelial cells. In addition to myeloid cells, Fes gene upregulation occurs during neuronal differentiation and accelerates neurite outgrowth in PC12 cells. Whether alternative *cis*-acting elements control Fes expression in different cell types will require further investigation.

Conclusions

The *c-fes* proto-oncogene encodes a unique cytoplasmic protein-tyrosine kinase involved in myelopoiesis, angiogenesis, and CML progression. Fes is also expressed in mammary and gut epithelium, where it may serve as a tumor suppressor. Although the sequence, structure, and position of the SH2 and kinase domains found in Fes share close homology with other nonreceptor tyrosine kinases, the N-terminal F-BAR region is structurally distinct. The presence of CC oligomerization domains within this region suggests a mode of kinase regulation and substrate recruitment unique to this tyrosine kinase family. Fes is associated with terminal differentiation of myeloid hematopoietic cells, as opposed to other tyrosine kinases that drive proliferation and survival. Work implicating Fes in the regulation of vascular endothelial cell migration suggests a role in tumor angiogenesis. Fes may also regulate cell survival and apoptosis during mammary gland differentiation, as well as neurite outgrowth. Loss of Fes function and expression in colorectal cancer suggests a key role for this unique kinase in the maintenance of epithelial tissue architecture as well.

Glossary

CCT Chaperonin containing Tcp-1, eukaryotic group II chaperonin.

Chaperonin Nanocage-forming molecular chaperone.

Cpn10 Chaperonin of 10 kDa, chloroplast GroES homolog.

Cpn60 Chaperonin of 60 kDa, chloroplast group I chaperonin.

GroEL Growth E locus, large gene, bacterial group I chaperonin.

GroES Growth E locus, small gene, bacterial group I chaperonin cofactor.

Hsp10 Heat shock protein of 10 kDa, mitochondrial GroES homolog.

Hsp60 Heat shock protein of 60 kDa, mitochondrial group I chaperonin.

Hsp70 Heat shock protein of 70 kDa, a major heat shock protein.

Htt Huntingtin, a human neuronal poly-glutamine protein.

Molecular chaperone Cellular protein folding catalyst/mediator or assembly factor.

PhLP Phosducin-like protein, a co-chaperone of group II chaperonins.

Prefoldin/GimC Co-chaperone of group II chaperonins.

RuBisCO Ribulose biphosphate carboxylase/oxygenase.

TIM barrel Triose phosphate isomerase fold, an eight-stranded β -barrel.

Thermosome Archaeal group II chaperonin.

TRiC Tcp-1-containing ring complex, eukaryotic group II chaperonin.

VHL protein Van Hippel Lindau protein, a human Trp/CCT substrate.

WD-40 repeat Forty-Residue repeat with a characteristic Trp-Asp motif; forms one blade of a β -propeller structure.

Introduction

The folding and assembly of newly synthesized proteins is a process of fundamental biological significance. *In vitro*, many proteins can fold spontaneously, solely based on the steric information contained in their amino acid sequences. However, under the highly crowded conditions prevailing in the cell, the efficiency of protein folding is often limited by aggregation, that is, the association of non-native states that expose hydrophobic amino acid residues and regions of unstructured polypeptide backbone to the solvent. Molecular chaperones, themselves proteins, have evolved to prevent aggregation and promote proper folding. They act by recognizing and shielding the non-native states of newly synthesized proteins and of pre-existent proteins that have unfolded under stress conditions, such as heat stress. Several classes of chaperones act as adenosine triphosphate (ATP)-driven molecular machines, including the members of the Hsp70 and Hsp90 families, the AAA+ proteins, and the chaperonins. In the following, the structure and function of the chaperonins will be discussed in greater detail.

Architecture of Group I and Group II Chaperonins

Chaperonins are found in all domains of life, in archaea, eubacteria, and eukaryotes, forming a group of evolutionary conserved proteins consisting of subunits of ~55-kDa molecular weight. These proteins form 800–1000-kDa double-ring complexes with seven to nine subunits per ring. Each subunit consists of an equatorial, an intermediate, and an apical domain. Both N- and C-termini of the sequence are located in the equatorial domain and thus the intermediate domain is inserted into a loop segment of the equatorial domain, while the apical

domain represents an insertion into the intermediate domain. The ATP-binding pocket is located in the equatorial domain, which has a unique ATPase fold only found in chaperonins. The equatorial domains also form the interface between the two rings. The intermediate domains are positioned on top of the equatorial domains, connecting them with the apical domains which form the pore-like opening of the complex (Figure 1).

Two groups of chaperonin can be distinguished: group I chaperonins and group II chaperonins. Group I chaperonins are found in eubacteria and the organelles of eubacterial origin, mitochondria and chloroplasts. These chaperonins are named growth E locus, large gene, bacterial group I chaperonin (GroEL), heat shock protein of 60 kDa (Hsp60), and chaperonin of 60 kDa (Cpn60), respectively. All group I chaperonins consist of seven-membered rings. GroEL and Hsp60 rings are homomeric, whereas Cpn60 contains two types of homologous subunits, designated α and β . Apparently, the eukaryotic group I chaperonins are part of the prokaryotic protein folding machinery that has been maintained during evolution from the endosymbiont precursors of mitochondria and chloroplasts, proteobacteria, and cyanobacteria, respectively. Catalysis of folding by group I chaperonins strongly depends on a heptameric cofactor complex named growth E locus, small gene, bacterial group I chaperonin cofactor (GroES) in bacteria (Hsp10 and Cpn10 in mitochondria and chloroplasts, respectively). Structural analysis revealed that binding of GroES to a GroEL ring creates a large internal cavity that provides a secluded folding chamber for substrate proteins (Figure 1).

By contrast, the group II chaperonins in the cytosol of archaea and eukaryotes do not require such a cofactor but instead carry α -helical extensions on their apical domains. The crystal structure of the archaeal chaperonin, the so-called thermosome, showed that these extensions can form an in-built,

Figure 1 Structures of (a) group I and (b) group II chaperonins. On top, the structure of the GroEL₁₄ ADP₇-GroES₇ complex is shown (Protein Data Bank (PDB): 1PF9). The lower, so-called *trans*-GroEL₇ ring has no nucleotide bound and the subunits expose the substrate binding cleft toward the ring opening. The upper GroEL₇ ring has ADP bound in the crystal structure. The GroES₇ heptamer sits on top (the *cis* ring), indicated in blue. In two GroES subunits, the equatorial, intermediate, and apical domains are indicated in red, green, and blue, respectively. On the right, a vertical cross section through the complex is shown, highlighting the protein-folding chamber in the *cis* ring. The Gly-Gly-Met sequence repeats at the C-termini (indicated) are disordered in the crystal structure and thus not shown. These flexible tails presumably point into the cavity. Below, electron microscopy reconstructions of the thermosome from *Methanococcus maripaludis* are shown (PDB files 3IYE and 3IYF). The corresponding data for TRiC/CCT are very similar, but at lower resolution. The subunits are color-coded to show the subunit arrangement in TRiC/CCT. Two pairs of the subunits make homomeric contacts across the ring-ring interface. For one of these subunits the domain structure is shown using the same color code as for GroEL. Note that the chaperonin subunits have a staggered arrangement in group I chaperonins but are directly opposed in group II chaperonins. The symmetrical ring arrangement in the group II chaperonin structures is presumably an experimental artifact caused by either the complete absence or high abundance of nucleotide. Kinetic data suggest that these chaperonins also assume asymmetrical conformations with one ring open and the other ring closed at physiological nucleotide levels.

iris-like lid above the cavity (Figure 1). Most group II chaperonins form eight-membered rings but some archaeal chaperonins consist of nine-membered rings. Most group II chaperonins are heterooligomeric: thermosomes were reported to contain up to three different subunit types; the eukaryotic cytosolic chaperonin TRiC/CCT comprises eight evolutionary conserved, paralogous subunits.

Besides the group I and group II chaperonins, several chaperonin homologs appear to adopt alternative assemblies

other than typical chaperonin cages. For example, one of the two chaperonins of *Mycobacterium tuberculosis* is dimeric in solution. Metazoans contain three chaperonin homologs, Bbs6, Bbs10, and Bbs12, which are implicated in humans in the inherited disease, Bardet-Biedl syndrome. Such unusual chaperonin subunits might become incorporated into the ring complexes of canonical chaperonins, adapting them to specific substrate proteins.

Bacterial GroEL – Structure and Mechanism

GroEL of *Escherichia coli* is by far the best-studied chaperonin. A plethora of structural and functional data is available for this complex. The function of GroEL is based on an intricate ATP- and GroES-dependent conformational cycle, which involves both chaperonin rings (Figure 2). In the nucleotide-free state, the apical domains of GroEL expose a hydrophobic cleft suited for the binding of short hydrophobic peptides in an extended or amphiphilic α -helical conformation. This state is characterized by a collapsed ring conformation with only small internal cavities. ATP binding primes the rings for a large conformational change in the subunits, specifically an upward and clockwise turning motion of the apical domains, which is completed and stabilized upon binding of the GroES heptamer (Figure 1). The ATP hydrolysis reaction exhibits positive cooperativity within individual rings, that is, hydrolysis of ATP bound to one subunit triggers ATP hydrolysis in neighboring subunits, and negative cooperativity between rings, such that only one ring is active at a time. In the absence of bound substrate, GroES is a potent inhibitor of ATP hydrolysis by GroEL, preventing nonproductive cycling. The GroES-binding site partially overlaps with the substrate-binding site; thus, the binding of GroES promotes the displacement of the substrate into the newly formed interior cavity. This cavity is large enough to accommodate proteins of ~60 kDa and thus appears to be sufficient for the great majority of the identified GroEL substrates. Some larger proteins may utilize GroEL for aggregation prevention but do not undergo global encapsulation for folding. Following GroES binding, the ATP in the seven GroES-interacting subunits of GroEL (the so-called *cis* ring) is hydrolyzed (Figure 2). During this period of ~10 s, the enclosed substrate protein is free to fold in the *cis* cavity. Upon completion of ATP hydrolysis in the *cis* ring, the opposite (*trans*) ring becomes primed for a new cycle of substrate and nucleotide binding. Specifically, ATP binding to the *trans* ring elicits a negative allosteric signal that causes the dissociation of the ligands from the *cis* ring, 7ADP and GroES (ADP, adenosine diphosphate), thereby allowing substrate to exit the folding cage. Incompletely folded protein molecules will rebinding rapidly, either to the same or to another GroEL ring, to undergo a new attempt at folding in the chaperonin cage (Figure 2). Some proteins have been observed to require multiple interaction cycles with GroEL for completion of folding.

The crystal structure of a GroEL₁₄ ADP₇ GroES₇ complex (Figure 1) showed that the interior wall of the folding cage has mainly polar character and contains numerous charged side chains; the hydrophobic patches on the apical domains are buried at the interface to GroES. Thus, the folding substrate may experience conditions of infinite dilution, provided that

Figure 2 Protein-folding cycle of GroEL–GroES. Kinetically trapped or misfolded substrate protein may be delivered to GroEL by upstream chaperones such as DnaK–DnaJ (the Hsp70 chaperone system) (1). Upon binding to GroEL, substrate may undergo local unfolding, occupying multiple apical domain-binding sites of GroEL. ATP-dependent domain movement of the apical GroEL domains can result in a stretching of tightly bound regions of substrate and in release and partial compaction of less stably bound regions (2). Compaction is completed upon global substrate encapsulation by GroES (3). Subsequently, folding proceeds in the chaperonin cage (4). ATP binding to the opposite ring then initiates a new folding cycle, releasing GroES and allowing substrate exit (5). Incompletely folded substrates might rebound to GroEL. Note that binding of a second substrate molecule to the open ring of GroEL in steps (4) and (5) as well as the transient formation of a symmetrical GroEL–GroES₂ complex are omitted for simplicity. N, native state; I, folding intermediate. Modified from F Ulrich Hartl & Manajit Hayer-Hartl (2009) Converging concepts of protein folding *in vitro* and *in vivo*. *Nature Structural and Molecular Biology* 16: 574–581.

sufficient water was enclosed (water can freely access the cage). In this model, known as the Anfinsen cage model, the protein is thought to fold inside the cage at the same speed and efficiency as it would in bulk solution in the absence of aggregation, as confirmed for the 30-kDa protein rhodanese. However, this model cannot explain how GroEL–GroES accelerate the folding of certain proteins above their rate of spontaneous folding (measured in the absence of rate-limiting aggregation). GroEL-dependent substrates typically are ~35–60 kDa in size and have complex domain topologies. Such proteins tend to accumulate kinetically trapped folding intermediates that need activation to proceed rapidly toward the native state. Assuming that kinetic trapping is caused by the presence of non-native intra-chain contacts, local unfolding upon substrate binding to multiple GroEL subunits or mediated by the ATP-dependent expansion of the GroEL ring may destabilize these misfolded states (Figure 2). Accordingly, iterative cycles of unfolding followed by folding trials in the chaperonin cage (iterative annealing) may increase the rate and/or the yield of the folding reaction. However, accelerated folding of proteins such as RuBisCo (~50 kDa) is also observed upon single-round encapsulation in a noncycling GroEL variant, arguing against iterative annealing as the mechanism of rate acceleration and suggesting that the physical environment of the cage is critical for this effect. Indeed, geometric confinement in the cage may significantly reduce the number of accessible

conformational states, thereby entropically destabilizing flexible folding intermediates and promoting their conversion to the native state. Furthermore, the cavity walls are lined with charged side chains whose electric potential may be difficult to dissipate through solvation by water in the presence of large enclosed proteins. As charged residues are normally located at the surface but not in the hydrophobic interior of natively folded proteins, the charged groups on the cavity walls might thus help to drive folding of the substrate into a near-native state.

Another feature frequently found in bacterial group I chaperonins (and also in group II chaperonins) are flexible C-terminal sequences extending into the cavity, often containing multiple Gly–Gly–Met repeats. *In vitro*, the length of these extensions modulates the folding efficiency, apparently by adapting the effective volume of the cage to substrate size.

The Eukaryotic Chaperonin TRiC/CCT

The paradigm for group II chaperonins is the eukaryotic cytosolic chaperonin TRiC (alternatively named CCT). X-ray crystallographic data are available for the less complex thermosome but only little is known about the folding substrates and the function of these chaperonins. The subunit sequence within each ring of TRiC/CCT and also the relative orientation

of the two rings appears to be invariant, but the exact arrangement of the eight subunits around the ring has not yet been unequivocally determined.

Despite the close structural homology between group I and II chaperonin subunits, the architecture of their complexes deviates markedly. In group I chaperonins, the equatorial domains are interdigitated; each subunit contacts two subunits in the opposite ring. In group II chaperonins the subunits are directly opposed, limiting the contacts across the equator to one subunit (Figure 1). Furthermore, the closure of the in-built lid in group II chaperonins requires a regulatory mechanism distinct from the association and dissociation of the GroES cofactor in group I chaperonins. Similar to GroEL, ATP hydrolysis within one ring exhibits positive cooperativity, whereas negative coupling occurs between the rings in TRiC/CCT. However, it is rather the ATP hydrolysis transition state than ATP binding that converts the open to the closed conformation, which is characterized by the association of the apical domain extensions and formation of the internal cavity. In this conformation, the putative substrate-binding sites in the apical domains become buried at the subunit-subunit interfaces. Electron microscopy suggests that the conformational transition proceeds sequentially around the ring, perhaps reflecting different ATP affinities and hydrolysis activities of the distinct TRiC/CCT subunits. In the open state, the subunits assume an extended, relaxed conformation, in which the apical domains are readily accessible for substrate.

Electron microscopic structures of TRiC/CCT in complex with substrates suggest that multiple subunits are involved in substrate binding and that these contacts occur in a specific binding pattern, providing a possible explanation for the non-redundancy of the TRiC/CCT subunits. Based on the conservation of signature residues in individual subunits, it has been suggested that the substrate interfaces in the apical domains of TRiC/CCT are rather flat and polar in character, more suited for interactions with late or near-native folding intermediates than with the molten globule-like states recognized by GroEL. However, similar to GroEL, TRiC/CCT also recognizes short hydrophobic sequence motifs in model substrates such as Van Hippel Lindau (VHL). Probably, the TRiC/CCT complex employs a mosaic of binding sites for folding intermediates with distinct physico-chemical properties.

Cellular Functions of Chaperonins

In bacteria and eukaryotes, the chaperonins participate in the folding of 10–15% of the cellular proteins, making them one of the central components of the folding machinery besides Hsp70 and Hsp90. Both GroEL/GroES and all TRiC/CCT subunits are essential in *E. coli* and *Saccharomyces cerevisiae*, respectively.

Proteomic analysis indicated that ~250 different cytosolic proteins interact with *E. coli* GroEL. The molecular weights of most of the GroEL interactors fall in the range of 20–50 kDa, matching the cavity size of GroEL. Majority of GroEL-dependent proteins have complex α/β or $\alpha + \beta$ topologies, with a predominance of the triose phosphate isomerase (TIM) barrel fold. For example, the large subunit of RuBisCO, the obligate bulk substrate of the chloroplast group I chaperonin, has such a TIM barrel fold. Similar to the large RuBisCO subunit, many GroEL substrates form homo- or hetero-

oligomeric assemblies. As in the case of RuBisCO, the monomeric precursors of some of these proteins may be structurally labile, resulting in a need for specific chaperones acting downstream of chaperonin in mediating assembly.

TRiC/CCT was first recognized as the essential folding catalyst of the cytoskeletal proteins actin and tubulin, both of which are unable to fold spontaneously. Today, it is clear that many other eukaryotic proteins are also substrates of TRiC/CCT. In recent proteomics and genomics studies, more than 100 potential TRiC/CCT substrates were identified. Bioinformatic analysis revealed that multidomain proteins ranging in size between 40 and 75 kDa and proteins rich in regions of β -strand propensity are over-represented in the TRiC/CCT interactome. These proteins are predicted to be slow folding and aggregation prone. Many TRiC/CCT substrates contain β -propeller domains with a characteristic WD-40 repeat pattern, a structural building block frequently found in eukaryotic proteins. Many of the TRiC/CCT substrates are subunits of important eukaryotic complexes, such as the anaphase-promoting complex, the nuclear pore complex, and the septin complex. TRiC/CCT is also implicated in the suppression of toxicity arising from the amyloid-forming protein huntingtin, which causes neuronal cell death in Huntington's disease.

Although TRiC/CCT was also found associated to translating ribosomes, it is assumed that other chaperones generally act upstream in stabilizing nascent chains and mediating their transfer to TRiC/CCT. A molecular chaperone specialized for the cooperation with group II chaperonins is prefoldin/GimC, a jelly fish-shaped complex, which can stabilize folding substrates between six tentacle-like coiled-coil extensions. The prefoldin complex is conserved in both archaea and the eukaryotic cytosol. The archaeal version contains two types of subunits; the eukaryotic has six subunits, mirroring the increase in complexity in subunit composition that occurred during evolution from the thermosome to TRiC/CCT. Electron microscopy of the prefoldin-TRiC/CCT complex suggests that the substrate might be handed over directly into the folding cavity. Deletion of prefoldin subunits impairs actin and tubulin function to varying degrees, implicating prefoldin in the folding of these TRiC/CCT substrates. Besides prefoldin, the Hsp70 chaperone acts upstream of TRiC/CCT in eukaryotes. An electron microscopic structure of the TRiC/CCT-Hsp70 complex indicated that Hsp70 specifically recognizes the apical domain of one chaperonin subunit for the handover of substrates.

Another class of co-chaperones of TRiC/CCT are the phosducin-like proteins (PhLPs), which are present in several isoforms. In contrast to prefoldin, the PhLPs form stable complexes with the chaperonin and could potentially influence chaperonin function directly, for example, by enlarging the cavity size or regulating the ATPase activity of TRiC/CCT. Genetic studies in *S. cerevisiae* point to an involvement of PhLPs in actin and tubulin folding. A role of PhLPs in folding of the α -subunit of trimeric G-proteins, a β -propeller protein, has also been demonstrated.

Conclusions

The chaperonins constitute an essential part of the cellular folding machinery in every organism, with the GroEL-GroES

complex currently being the best-characterized molecular chaperone system. In eukaryotes, the TRiC/CCT complex is a central element of the cellular protein quality control network, intricately involved in processes that contribute to aging and human disease. Of particular interest for future studies is a detailed comparison of the folding mechanisms of spontaneous and chaperonin-assisted folding.

Glossary

Bioluminescence The light that results from a chemiluminescent reaction in a living organism or from components of a living system, such as firefly tails.

Chemiluminescence The light that is emitted from certain chemical reactions without the production of significant heat.

Flavin mononucleotide Riboflavin-5'-phosphate, the 5'-phosphate derivative of vitamin B₂.

Flavin monooxygenase An enzyme that employs a flavin coenzyme to split the two atoms of molecular

oxygen apart, depositing one in an organic substrate as a hydroxyl group and the other in water.

Fluorescence The phenomenon of light emission that occurs from certain molecules as they return to the ground state from the lowest excited singlet excited state. Population of the singlet excited state is the result of absorption of energy from incident light.

Luciferase An enzyme that catalyzes a reaction that emits visible light with high efficiency. Luciferases are exceptionally diverse, many with no evolutionary relationship to the others.

Chemiluminescence and bioluminescence are terms that refer to the same physical process of light emission without heat. Bioluminescence is the process by which a living system or components isolated from a living system, such as a firefly tail, carry out a series of reactions that result in emission of light. Chemiluminescence is the same kind of process, but involving molecules that are not of biological origin. Chemiluminescence should be distinguished from incandescence, which occurs at high temperatures. Both bioluminescence and chemiluminescence are well known to the public, and both hold great fascination for all observers. Light without heat has intrigued people since the beginning of recorded history, and surely before.

Fluorescence: The Underlying Property

Fluorescence is a characteristic common to molecules formed as a result of chemiluminescent and bioluminescent reactions. At normal ambient temperatures, the vast majority of molecules exist in what is known as the ground state. However, under certain conditions, such as absorption of light energy, a molecule may be converted into an excited state. For fluorescent molecules, the excited state can return to the ground state by emitting energy as light. Virtually, all molecules are fluorescent to some extent, but most emit such a small amount of light that sensitive instruments are required to detect it. A graphic description of fluorescence is shown in Figure 1.

In the case of fluorescence, the energy input is the absorption of light. The chemical characteristics of a molecule will determine which wavelengths (color) of light it will absorb. As in the ground state, the excited state will have multiple vibrational modes at discrete energy levels. At normal ambient temperatures, most of the molecules will be in the lowest vibrational energy level, so following absorption of the input energy, the molecules will relax to the lowest vibrational level of that excited state. Excited states tend to be very unstable,

with lifetimes from the nanosecond to picosecond range. There are many ways for a molecule to return to the ground state. In solution, the excited molecules may collide with other molecules in solution and impart energy through the collisions, thereby increasing the vibrational and translational energies of the other molecules while returning to the ground state. Alternatively, some molecules, referred to as fluorescent molecules, have the ability to return to the ground state by emission of light. Note that the emitted light will be of lower energy (red-shifted in the spectrum) relative to that of the input energy due to the relaxation of the excited state. This effect is known as the Stokes shift.

Chemiluminescence: Fluorescence from a Chemical Reaction

In the case of chemiluminescence, the input energy is derived from the making and breaking of bonds that occur during a chemical reaction. Other than this important detail, fluorescence and chemiluminescence result from the same fundamental characteristics of the molecules involved. For a reaction to be chemiluminescent, one of the products must be fluorescent, and the chemical step that results in generation of the fluorescent product must be of sufficiently high energy to result in formation of the excited state. Therefore, the efficiency of light emission from a chemiluminescent reaction is the product of the efficiencies of each step. That is, the chemiluminescent quantum yield, Φ_{CL} , or the yield of photons per molecule of reactant consumed in the reaction:

$$\Phi_{CL} = \Phi_R \times \Phi_{CE} \times \Phi_F$$

All of these efficiencies have values between 0 and 1. The reaction yield (Φ_R) is the chemical yield of the correct products, rather than the products of side reactions, which may not be fluorescent, and is typically near 1. The chemical excitation yield (Φ_{CE}) is the fraction of the fluorescent product molecules that are produced in the excited state, rather than the ground

state. To be considered a chemiluminescent reaction, this value should be 10^{-3} or greater. Finally, the fluorescence quantum yield (Φ_F) is the proportion of those molecules that are produced in the excited state that return to the ground state by emission of light rather than by collisional quenching or some other process, as depicted in **Figure 1**. The fluorescence quantum yield is typically 0.1 or greater. Conditions that impact any of these three factors will impact the overall yield of light from the reaction.

In some cases, product molecules are produced with exceptionally high chemical yield in the excited state, but the product is itself nonfluorescent (very low Φ_F). In these cases, the yield of luminescence can be increased dramatically by addition of a highly fluorescent molecule to the reaction, which can, by a process called energy transfer, accept the energy from the excited product to become excited itself. The overall chemiluminescence quantum yield in such cases becomes

$$\Phi_{CL} = \Phi_R \times \Phi_{CE} \times \Phi_F \times \Phi_{ET}$$

where Φ_{ET} is the efficiency of energy transfer from the primary excited state produced in the chemical reaction to the acceptor, which then emits with the efficiency given by Φ_F . The chemiluminescence quantum yields in some sensitized chemiluminescent reactions can be very high indeed, approaching 1.

Much research has been reported on the chemiluminescence properties of a wide array of peroxides, especially the cyclic peroxides such as the dioxetanes. Tetramethyldioxetane will decompose to yield two molecules of acetone, one in the singlet excited state and the other in the triplet (Figure 2). Of

Figure 1 Diagram showing the processes of generation of the excited state and return of the excited state to the ground state.

Figure 2 Chemiluminescent decomposition of tetramethyldioxetane. The first step of the reaction is the hemolytic cleavage of the oxygen–oxygen bond, followed by hemolytic cleavage of the carbon–carbon bond to yield the diradical, which recombines to form acetone in the excited state. In the absence of the dye 9,10-dibromoanthracene, the reaction is dark. However, the dye can accept the energy from the excited state carbonyl to yield the excited state of the dye, which returns to ground state with the emission of light.

course, acetone is nonfluorescent, so the decomposition reaction is essentially dark. However, if 9,10-dibromoanthracene or 9,10-diphenylanthracene is added to the reaction, intense light emission is detected as a result of the energy transfer from the excited-state acetone product to the fluorescent dye, dibromoanthracene (DBA) or diphenylanthracene (DPA).

These and related technologies have found wide use in the form of chemiluminescence-based diagnostics and other applications. Perhaps one of the best-known applications is the light-stick technology used by campers and hikers, and for fun and safety during Halloween. The light stick consists of a sealed, flexible plastic tube containing a solution of oxalic phthalate ester and a sealed glass vial containing a solution of hydrogen peroxide. Bending of the plastic tube will cause the glass vial to break, mixing the two solutions. The hydrogen peroxide will oxidize the ester, yielding two molecules of phenol and one molecule of 1,2-dioxetane-3,4-dione. The dioxetane will decompose to yield two molecules of carbon dioxide in the excited state. By including a dye sensitizer in the solution, the energy of the excited state carbon dioxide will result in light emission (see **Figure 3**). The color of the light emitted is determined by the fluorescence properties of the dye used in the light stick and can range from blue to red. Examples of dyes used are shown in **Figure 3**. One characteristic common to most fluorescent compounds and demonstrated in these examples is a system of conjugated double bonds.

Bioluminescence: Chemiluminescence from a Biological Source

Bioluminescence reactions, unlike chemiluminescence, require an enzymatic catalyst for the reaction to occur. These enzymes are generically referred to as luciferases. Even though they have the same name, they catalyze vastly different reactions. For comparison, other groups of enzymes that have a common name, such as proteases, all catalyze the same kind of reactions. Proteases all hydrolyze peptide bonds, but luciferases catalyze reactions on completely different substrates, and they have no evolutionary relationship. Firefly luciferase, bacterial luciferase, and Renilla luciferase catalyze different reactions, having in common only the fact that light is emitted from a product of

Figure 3 The chemistry of the light stick. The reaction that occurs in a light stick upon breaking the glass ampule and allowing the two solutions to mix is shown in panel (a). The oxalic phthalate ester is oxidized to yield two molecules of phenol and one molecule of the dioxetane. In panel (b), the dioxetane decomposes by the same mechanism shown in [Figure 2](#) to yield two molecules of carbon dioxide. The excited-state carbon dioxide transfers energy to the dye to yield the excited state of the dye, which in turn emits light. The color of the light is determined by the chemistry of the dye. Three examples are shown in panel (c), spanning the spectrum from red to blue.

Figure 4 Proposed mechanism of the firefly luciferase reaction. The luciferin reacts with ATP to form the luciferyl adenylate, thus preparing the molecule for reaction with oxygen.

Figure 5 Proposed mechanism of the firefly luciferase-catalyzed reaction. The luciferyl adenylate (Figure 4) reacts with molecular oxygen, eliminating the AMP and forming the cyclic peroxide dioxetanone structure. The dioxetanone then decomposes by homolytic cleavage of the O–O and C–C bonds, liberating CO₂ and yielding the excited state of the oxyluciferin. Light emission occurs as the excited state returns to ground state.

the reaction. It is therefore very important when discussing bioluminescence to stipulate the biological source of the enzyme.

There are many examples of bioluminescence that resemble the nonbiological chemiluminescence reactions described previously. For example, the reaction that occurs in the tail of the firefly is very similar to that of the light stick, but unlike the light stick, the firefly reaction requires the participation of an enzyme, firefly luciferase. As with chemiluminescent reactions, the firefly luciferase-catalyzed reaction has found numerous practical applications, primarily due to the involvement of adenosine triphosphate (ATP) in the reaction (Figure 4). Many of these applications involve accurate and sensitive analysis of ATP levels within samples. The role of the ATP is to activate the carboxyl group of the firefly luciferin, the substrate for the luciferase-catalyzed reaction. As a result of this adenylation reaction, the luciferyl adenylate is now poised to react with molecular oxygen, eliminating adenosine monophosphate (AMP) and forming the dioxetanone intermediate (Figure 5). The dioxetanone ring then decomposes by a mechanism similar to that shown in Figure 2, ultimately yielding CO₂ and the excited state of the product oxyluciferin, which emits light as it returns to ground state.

Different species of firefly emit light of different colors, but they all appear to use the same substrate luciferin, and there appear to be no energy transfer systems involved. At present, the detailed mechanism by which the insects emit light of different color is unknown, but it surely has to do with the details of the interactions of the excited state with the luciferase enzyme, since the enzymes are slightly different between the species. The color of the light emitted ranges from green to red, and the quantum yield of these reactions approaches 1.

Unlike firefly luciferase, which is a single polypeptide and employs ATP and a special substrate firefly luciferase, bacterial

luciferase is a heterodimer ($\alpha\beta$) consisting of two similar but nonidentical polypeptides. In bacterial luciferase, there is a single active center on the α -subunit, but both subunits are required for the high quantum yield reaction. The substrates for the bacterial luciferase reaction are reduced flavin mononucleotide, molecular oxygen, and a long-chain saturated aldehyde. The enzyme formally is a flavin monooxygenase, catalyzing the cleavage of molecular oxygen and inserting one atom of oxygen into a substrate and the other into water. The mechanism of light emission in the bacterial luciferase-catalyzed reaction is still under debate, but there is general agreement regarding most of the reaction. In the first step of the reaction, reduced flavin mononucleotide (FMNH₂) reacts with O₂ to yield a reduced flavin peroxide (step 1, Figure 6). In the second step, the peroxide reacts with the aldehyde substrate to form the tetrahedral intermediate shown in Figure 6, step 2. There is general agreement in the field that this tetrahedral intermediate forms in the reaction, but how the intermediate decomposes to yield the excited state is under debate. One possible mechanism is shown in step 3 of Figure 6.

The identity of the emitter in the bacterial bioluminescence has been difficult to identify unambiguously because the product of the reaction, oxidized flavin mononucleotide, although fluorescent in solution, is nonfluorescent when bound to the luciferase. Various lines of evidence suggest that the emitter in the reaction is the flavin pseudobase shown in step 3 of Figure 6. The primary excited state, however, must be some other molecule, possibly the excited carbonyl shown in step 4 of Figure 6. In some species of bioluminescent bacteria, light emission from the living bacteria is significantly blue-shifted compared to that from the purified luciferase enzyme. It has been shown that the blue light comes from another protein, the lumazine protein, which becomes excited through some

Figure 6 Proposed mechanism of the bacterial luciferase-catalyzed reaction, as described in the text.

form of interaction with the luciferase during the reaction. This is an example of an energy transfer process in a bioluminescence system, similar to the chemiluminescent examples described in Figure 3. But for the energy transfer to be efficient, it must occur in an energetically downhill direction. That is, the primary excited state must have an energy level higher than the excited flavin, which emits at a longer wavelength (lower energy) than does the lumazine protein. It is this fact, among others, that leads to the belief that the primary excited state in this reaction is likely to be an excited carbonyl, rather than the excited flavin. In the absence of the lumazine protein, energy transfer can occur to the flavin with emission from the excited flavin.

Another example of energy transfer in the bacterial bioluminescence system is from a yellow-emitting strain of *Vibrio fischeri*. These bacteria have a luciferase that emits blue-green light, similar to other bacterial luciferases, but *in vivo* and at temperatures of 20 °C or lower, the color of the light emitted is bright yellow. This color shift is the result of a yellow

fluorescence protein that has a highly fluorescent-oxidized flavin mononucleotide chromophore. It is interesting that the lumazine protein, which causes a blue shift, and the yellow fluorescence protein appear to be homologous and carry out similar functions of energy transfer but do so with different chromophores.

There are many other examples of bioluminescent and chemiluminescent reactions, many of which have found important and valuable uses. The green fluorescent protein that was isolated from jellyfish is a very important tool in the study of protein trafficking and other molecular imaging applications. In immunoassays, chemiluminescent and bioluminescent reactions offer sensitivity, but without the hazards of radioactive labels. In recent years, work in the field has become primarily focused on applications of the technology; by comparison, very little effort is being directed at a basic understanding of the mechanisms of the processes involved. As should be apparent from this brief overview, much remains to be learned.

Glossary

Electrogenic A process that produces an electric field due to net movement of charged species across a region of low dielectric strength such as a lipid bilayer membrane.

Electroneutral A process that results in no net charge change and does not produce an electric field.

Inner mitochondrial membrane The innermost membrane of mitochondria that houses the protonmotive electron transfer chain and adenosine triphosphate (ATP) synthase and separates the intermembrane space and matrix.

NAD(P)⁺ and NAD(P)H The oxidized and reduced form of nicotinamide adenine dinucleotide (phosphate).

NADH is produced by metabolic dehydrogenation reactions and is reoxidized by complex I of the respiratory chain.

NADPH is generated by reductants produced by photosystem I. They are donors/acceptors of two electrons and only one proton, but are sometimes shown in textbooks as NAD(P) and NAD(P)H₂.

Protonmotive force A protonmotive force is generated when protons move across a proton-impermeable barrier. It is a free energy term arising from an electrical charge difference and a pH difference across the barrier.

Thylakoid membrane The membrane within chloroplasts that house the photosynthetic electron transfer chain and ATP synthase.

Vectorial reaction A reaction in which the reactants are arranged spatially such that the reaction products are produced in a spatial manner.

Introduction

All living cells require energy to survive. The energy can be provided by food, by light, or, in diverse bacteria, by a myriad of possible environmental materials. These are used in large part to produce adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate. ATP is a stable and transportable intracellular energy source. Its hydrolysis back to ADP and inorganic phosphate releases energy that can be used to drive energy-requiring cellular processes. Some ATP synthesis occurs by classical enzymological mechanisms in which an energy-releasing chemical transformation is directly coupled to ADP phosphorylation within a single enzyme complex. Such substrate level phosphorylations occur in the glycolytic pathway. The majority of ATP synthesis, however, is usually associated with respiratory and photosynthetic processes that are catalyzed by complex redox enzymes embedded in ion-impermeable lipid membranes. The way in which these redox reactions are coupled to ATP synthesis is quite different to that of the substrate level phosphorylations because the energy-releasing redox reactions and energy-requiring ATP-synthesizing reactions do not occur within the same enzyme structures. Instead, they are coupled indirectly through an intermediary energy-storing proton gradient that is formed across the membrane in which they are embedded. This revolutionary chemiosmotic hypothesis of the mechanism of such coupling was first postulated by Peter Mitchell in 1961. It took many years before it, and its ramifications, gained widespread acceptance as the chemiosmotic theory, though even today some aspects of development of the ideas have remained controversial.

Historical Background

When Mitchell's first chemiosmotic paper appeared in 1961, it was already known that mitochondria and chloroplasts were primary producers of ATP and that the enzymes that harness the energy source and the ATP synthases are embedded in the same

lipid bilayer membranes. It was also known that the redox processes of respiration and photosynthesis could be uncoupled from each other, a phenomenon that was difficult to explain in terms of conventional enzymology. The prevailing ideas on how they are coupled involved mechanisms akin to those of substrate level phosphorylations or to the existence of a high-energy chemical intermediate (X~I) that could provide the linkage between the sources and sinks of energy. Despite considerable efforts to identify the nature of X~I, it remained elusive. Nevertheless, Mitchell's proposal that the coupling agent could instead be a proton gradient across the lipid membrane remained highly controversial and largely ignored.

It took more than a decade of experimental support, both from Mitchell himself and from other laboratories around the world, for his ideas to become accepted widely. Mitchell, together with his colleague Jennifer Moyle, left University in 1964 and set up the independent Glynn Research Institute in relatively remote Cornwall. There, together with a small research team, they set about testing the central tenets of the hypothesis by experiment. At the same time, Mitchell further developed his chemiosmotic hypothesis and placed it firmly within the context of the rapid developments that were occurring in the field of experimental bioenergetics. This work was published in two monographs, the 'Grey Books', in 1966 and 1968. These provided an expanded account of the chemiosmotic hypothesis and its application both to the coupling between respiratory and photosynthetic electron transfer and ATP synthesis and to energy-linked solute transport across membranes. Over the next decade it slowly gained support, often after acrimonious exchanges, and, in 1978, Mitchell was awarded the Nobel prize in chemistry for his work. The background and details of this remarkable case of difficulties of introduction of a radical idea into mainstream scientific thinking has been the subject of study and analysis by scientific sociologists and historians. The most important pieces of documentation have been archived and are held in Cambridge University Library.

The Central Features of the Chemiosmotic Theory

The chemiosmotic hypothesis was developed in the context of respiratory and photosynthetic electron flow, and the energetic coupling of these reactions to ATP generation and to active solute transport. It had four essential postulates in the form presented in the 1966 Grey Book, which can be paraphrased as:

1. The ATP synthase systems are membrane located and their normal function is to couple reversibly the translocation of protons across the membrane to the condensation reaction between ADP and inorganic phosphate to form ATP.
2. The electron transfer chains are also membrane located and their function is to couple reversibly the flow of reducing equivalents to the translocation of protons across the membrane.
3. The membranes also contain carrier systems that permit reversible transmembrane exchange of ions with protons or hydroxide ions. Their function is for osmotic and pH stabilization and for essential metabolite transport.
4. Systems of postulates 1–3 above are located in a coupling membrane that has a low permeability to protons and to anions and cations generally.

These features are discussed in more detail in a modern context below.

The Ion-Impermeable Membrane and the Protonmotive Force

A central component of chemiosmotic systems is a lipid bilayer membrane that separates two aqueous phases. In mitochondria, this is the inner mitochondrial membrane that separates the internal matrix from the intermembrane space and cytoplasm. In chloroplasts, it is the thylakoid membrane that separates the chloroplast lumen and stromal aqueous phases. In bacteria, it is the plasma membrane separating the cytoplasm from the external medium.

These membranes are bilayers of hydrophobic lipids that are impermeable to charged ions including protons. Hence, when protons are moved from one side to the other across the membrane barrier through the actions of the enzymes involved, a stable gradient of protons is established. This is akin to the charging of a capacitor in electronics and represents a form of stored energy. In this case, the stored energy is an electrochemical proton gradient and it has two energetic components, a pH gradient (ΔpH) and, because protons are charged, an electrical potential difference ($\Delta\psi$). Mitchell called this the protonmotive force (PMF or Δp). The PMF is the sum of the pH and electrical difference terms. It is usually expressed in units of electrical potential by conversion of the ΔpH term into the same units as $\Delta\psi$:

$$\Delta p = \Delta\psi - 2.303RT/F \Delta\text{pH}$$

where F = the Faraday constant ($96,487 \text{ J}\cdot\text{V}^{-1}\cdot\text{mol}^{-1}$), R is the gas constant ($8.3145 \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$), and T is temperature in K. At 25°C , $2.303RT/F \approx 59 \text{ mV}$ so that

$$\Delta p \text{ (in mV)} = \Delta\psi - 59\Delta\text{pH}$$

Δp is the free energy required to move protons across the membrane against the prevailing electrochemical proton

Figure 1 Components of PMF and their orientations in the coupling membranes of mitochondria and chloroplasts.

gradient, or the free energy available when moving protons back across the membrane to restore equilibrium.

The size of the electrical component is determined by the net charge difference and the capacitance of the membrane. The balance between the ΔpH and $\Delta\psi$ terms of Δp can be very different in different membrane systems. For example (Figure 1), in mitochondria under conditions when the Δp is maximal, the $\Delta\psi$ is typically close to 190 mV (positive on side facing the cytoplasm, Figure 1) and ΔpH is around 0.3 pH units (with highest pH in the matrix), resulting in a Δp of approx. 210 mV. In thylakoids in contrast, the Δp can be of a similar magnitude, but the $\Delta\psi$ -driven transfer of other ions across the membrane decreases the $\Delta\psi$ and allows the ΔpH component to rise substantially. The ΔpH can be up to 4 pH units (acidic in the lumen) but the $\Delta\psi$ is 30 mV or less (positive on the lumen side).

Membrane Location of Electron Transfer Chains and ATP Synthase

In order to be able to generate a PMF across the lipid bilayer membrane and to utilize it to generate ATP, it is essential that components of the enzymes involved must be arranged spatially in a specific manner within the membrane. This vectorial arrangement results in the redox reactions being coupled to the net movement of protons across the membrane. This in turn means that the free energy available from the redox reactions is not lost as heat but instead becomes stored in the form of the electrochemical proton gradient that they generate. The term 'chemiosmotic' was introduced to describe this type of process. Protein components of the ATP synthases embedded in the same membrane system provide a pathway for the return of the protons back across the membrane in a manner that drives ATP synthesis. The result is that the free energy available from the PMF-driven passage of protons across the membrane drives the otherwise endergonic synthesis of ATP.

The Vectorial Redox Loop

Importantly, Mitchell also proposed a model of the spatial arrangement and chemistry that would be required in a series of membrane-bound electron transfer components so that electron transfer would necessarily result in coupled proton translocation across the membrane. This elegant and simple proposal was termed the 'vectorial redox loop' (Figure 2(a)). It was postulated that the components of the redox chain alternated between electron carriers and hydrogen atom carriers and that

Figure 2 The redox loop proposal for coupling of electron transfer to transmembrane proton transfer. In its simplest form (a), an electron carrier (A) reduces an H-atom carrier (B). The site of reduction is close to the negative aqueous phase, so that reduction of B (shown here as a two-electron acceptor) results in proton uptake from that phase. The reduced form BH_2 then diffuses to the next acceptor C. Since C can only accept electrons and the reaction site is close to the positive aqueous phase, the two protons on BH_2 are released into this phase. The redox loop is completed by electrogenic transfer of the electrons to the next electron acceptor D that is located close to the negative aqueous phase. (b) This illustrates the same reactions, but in this case all reactions take place close to the negative aqueous phase. On oxidation of BH_2 , protons are released into a proton well that leads to the positive aqueous phase. The electrogenic movement of protons along this well to the positive aqueous phase generates the electric field. Most PMF-generating proteins tend to fall between these extremes of structure with both electron and proton transfer playing a part in electric field generation.

these were spatially arranged in a definite way in the membrane. The hydrogen carriers have redox-linked pK values such that reduction causes protonation and oxidation causes deprotonation. The hydrogen atom carriers are effectively mobile in the membrane, and diffuse from a site of reduction (and proton uptake) on one side of the membrane to a site of oxidation (and proton release) close to the opposite membrane surface. Since protons and electrons are transferred across the membrane together, the process is electroneutral. The loop is completed, however, by the transfer of the electrons back across the membrane *via* appropriately arranged electron carriers. In this case, uncompensated charge is moved across the membrane, and so an electric field is generated across the insulating membrane, i.e. the reaction is electrogenic. The net result is the appearance of one proton (with its positive charge) across the membrane for each electron passing through the redox loop, and the conversion of redox energy into an electrochemical potential gradient of protons, the PMF, across the membrane.

The classic example of a mobile hydrogen atom carrier behavior can be seen in the role of ubiquinone in mitochondria, and that of the related menaquinone and plastoquinone in bacterial and photosynthetic systems. A range of dehydrogenases and photosystems have quinone reduction sites that ensure that protons are taken up on one side of the membrane. As in **Figure 2(a)**, the quinone is reduced with two electrons and binds two protons to produce the reduced quinol form. The quinol then dissociates from its reduction site and physically diffuses to proteins with oxidation sites linked to the other membrane surface where it is reoxidized and the protons are released. Hydrophobic quinones play exactly this role as one part of the protonmotive reactions in mitochondria, chloroplasts, and many bacterial photosynthetic and respiratory chains.

In protonmotive enzymes, this simple redox loop notion is complicated by the role of the protein structures in the generation of the electrical and chemical potential components of the PMF. Usually, the catalytic sites where the key chemical and

redox transformations take place tend to be buried within the protein and can be located at any distance in terms of position across the lipid bilayer barrier. In this case, if protons are involved, channels in the protein structure must allow the protons into or out of the reaction site to the membrane surface. If the movement of the charged protons is not charge compensated by movement of counter ions then the proton movement, rather than the electron transfer, can be the primary electrogenic process. In the extreme example shown in **Figure 2(b)**, the highly localized redox loop takes place in reaction sites toward the negatively charged side of the membrane. As a result, the electron transfer steps do not generate an electric field. Instead, protons are released into a proton channel leading to the aqueous positive phase. The protons diffuse out electrogenically along the channel into the positive aqueous phase and in doing so generate an electric field. Hence, in this case it is proton movement, rather than electron transfer, which is electrogenic. Real protein systems tend to be somewhere between the extremes shown in **Figure 2**, with both electron and proton transfers playing a part in the generation of the electric field.

The Protonmotive Enzymes of Respiration and Photosynthesis

Tremendous progress has been made on understanding of the structures and mechanisms of the proteins and cofactors that are involved in generation and utilization of the PMF. In many systems, PMF generation is achieved by membrane-spanning enzymes that catalyze electron transfer and/or proton transfer toward buried catalytic centers as outlined in **Figure 2**. In many cases, the enzymes that oxidize the source of reductant are connected by a hydrophobic quinone to enzymes that pass the electrons to a terminal electron sink. The quinone often acts as a mobile hydrogen atom carrier as envisaged in the vectorial loop proposal.

However, several central enzymes have evolved additional protonmotive mechanisms that do not conform to the simple

Figure 3 The protonmotive electron transport chain of mitochondria. The mitochondrial inner membrane is shown separating the internal matrix space and the intermembrane space (IMS) and the numbers refer to the passage of two reducing equivalents along the chain of redox enzymes. The four major enzymes are complex I (NADH:ubiquinone oxidoreductase), complex II (succinate:ubiquinone oxidoreductase), complex III (ubiquinol:cytochrome *c* oxidoreductase) and, connected by cytochrome *c*, complex IV (cytochrome *c* oxidase). Reduction of ubiquinone by NADH in complex I is linked to translocation of four protons across the membrane. When ubiquinol is oxidized by complex II, two protons are released and a further two are translocated. At complex IV, molecular oxygen is reduced water with uptake of two protons from the matrix and a further two are translocated. Complex II has no protonmotive activity. Overall, for succinate and NADH oxidation by oxygen, 10 and six protons, respectively, are lost from the matrix and appear on the cytoplasmic side.

vectorial loop mechanism. In mitochondria, these enzymes are complex I (an NADH:ubiquinone oxidoreductase), complex III (a quinol:cytochrome *c* oxidoreductase), and complex IV (cytochrome *c* oxidase). Diverse homologs of these enzymes, which retain the additional protonmotive functions, are found in archaea, bacteria, plants, and fungi. Hence, it seems that these complex functions have evolved very early and have been retained throughout the diversity of evolution. The mechanism operative in complex III was itself explained by Mitchell in his ingenious extrapolation of the vectorial loop ideas to a Q cycle mechanism of action. For complexes I and IV, their protonmotive mechanisms remain controversial. The current understanding of the PMF-generating steps of the classical respiratory and thylakoids chains are summarized in Figures 3 and 4.

ATP Synthase and Coupling to the Proton Gradient

The enzymes that harness the energy of the PMF to produce ATP are the F_0F_1 -type ATP synthases. As their structure emerged, it became clear that the ATP-synthesizing catalytic centers, located in the F_1 domain, are at a considerable distance from the membrane-embedded protein domains, linked only by relatively narrow connecting structures. It is now clear that the PMF drives a membrane-embedded rotor of identical *c* subunits. This in turn drives the mechanical rotation of a central stalk within the catalytic F_1 subunits, which are themselves prevented from rotating by a peripheral protein stator that links the membrane-located and catalytic F_1 domains. The rotating stalk forces a cycle of conformational changes on the

Figure 4 The protonmotive electron transport chain of chloroplasts. The thylakoids membrane separates the stromal and lumen aqueous phases of the chloroplast. The numbers refer to the passage of two reducing equivalents along the chains. Photosystem II is activated by two separate photons that cause electrogenic charge separation by passage of two electrons across the membrane. This results in water oxidation to $\frac{1}{2} O_2$ with release of two protons into the lumen, together with plastoquinone reduction with uptake of two protons from the stroma. The plastoquinol diffuses along and across the membrane where it is oxidized by the cytochrome *bf* complex with release of two protons. The cytochrome *bf* complex is homologous to mitochondrial complex III and is capable of translocating a further two protons from stroma to lumen by a Q-cycle mechanism as indicated in the diagram. However, there is no consensus on whether this occurs under all conditions. The electrons pass via plastocyanin (PC) to photosystem I where two separate photons again cause them to traverse the membrane electrogenically, finally reducing NADP to NADPH with uptake of two protons from the stroma. Hence, with operation of a Q cycle, the passage of two electrons can result maximally in six protons (with their six positive charges) being lost from the stroma and appearing in the lumen.

active site polypeptides that power the endergonic process of condensation of ADP and inorganic phosphate to form and release free ATP. F_0F_1 -type ATP synthases are fully reversible and their overall effect is to bring into equilibrium the free energy of the PMF and that of the ATP/ADP reaction. In some systems, they act primarily in reverse to generate a PMF by hydrolyzing ATP synthesized elsewhere.

The Proton Circuit and Stoichiometry of ATP Synthesis

The operation of the respiratory or photosynthetic electron transfer chains with the ATP synthases, linked through the PMF, creates a proton circuit that allows the energy released from the exergonic electron transfer to drive endergonic ATP synthesis. The yield of ATP synthesis is then governed by the numbers of protons translocated across the membrane by the components involved.

For the mammalian respiratory chain (Figure 3), it is generally agreed that oxidation of NADH through complexes I, III, and IV is coupled overall to the net transfer of 10 H^+ across the mitochondrial inner membrane. Succinate oxidation through complexes II, III, and IV is coupled to the net transfer of 6 H^+ . For the ATP synthase, one complete rotation of the rotor results in synthesis of three ATP inside the mitochondrial matrix. The number of protons required for a full rotation is governed by the number of subunits that comprise the membrane-embedded ring of identical subunits (the *c* subunits), since one proton is used to rotate this ring by one subunit. It has

been found that the c ring is composed of different numbers of subunits in different organisms. For example, yeast mitochondrial ATP synthase has 10 c subunits but the mammalian mitochondrial form has only eight.

A further consideration in eukaryotic systems is that transfer of each ATP out of the mitochondrial matrix into the cytoplasm occurs by the action of transporters (see below) that exchange one ATP for an ADP and a phosphate from the cytoplasm. In doing this, one H^+ of the proton gradient is also transferred back into the mitochondrial matrix. Hence, the total number of protons required to produce three molecules of ATP in the cytoplasm is given by the number of c subunits plus the three protons required to export them into the cytoplasm.

For example, the maximum extent of synthesis of ATP by oxidation of glucose in mammalian cells can be calculated as follows. Full oxidation to CO_2 and water, catalyzed by the enzymes of glycolysis and the citric acid cycle, results overall in the production in the cytoplasm of two molecules of ATP by substrate-level phosphorylation and two molecules of NADH. The NADH are transported in most cells into the mitochondrial matrix where another eight NADH are produced by the citric acid cycle, together with two guanosine triphosphates (GTPs).

Hence, overall, full oxidation of one glucose can provide the respiratory chain with 10 NADH and also, at the step of succinate oxidation in the citric acid cycle, two succinates that are oxidized to fumarate by complex II. The oxidation of the 10 NADH and two succinates by the protonmotive respiratory chain will result in 112 H^+ translocated across the inner mitochondrial membrane. Since the mammalian ATP synthase has eight subunits in its c ring, this means that synthesis of three ATP will require $8 + 3 = 11$ protons. Hence, the respiratory chain could maximally produce slightly in excess of 30 ATP in mammalian cells.

Under conditions close to what might be expected physiologically in a mammalian cell (pH 7; 10 mM Mg^{2+} ; 10 mM phosphate), the equilibrium constant for the reaction

is approximately $10^{-5} (M^{-1})$, that is, strongly in favor of ADP with a positive ΔG_o of $\approx +29 \text{ kJ} \cdot \text{mol}^{-1}$. As stated above, the maximum PMF is typically around +210 mV, which in the same units is $\approx 20 \text{ kJ} \cdot \text{mol}^{-1}$. Since 3.66 protons are used to produce one ATP in the cytoplasm (ATP_{cyt}), the fully coupled overall reaction is

This would have a net ΔG of around $-45 \text{ kJ} \cdot \text{mol}^{-1}$, so that the ATP synthase will drive the reaction very much in favor of ATP. In practice, the PMF in active, living cells is not held at this maximum value and, in addition, there are processes that cause some of the protons to leak back across the membrane without passing through the ATP synthases. Hence, the yield of ATP, and the ratio of ATP/ADP achieved, is somewhat lower. Nevertheless, mitochondria have been shown to be able to drive the cytoplasmic ATP/(ADP.phosphate) ratio under similar conditions to at least 10^5 , with ATP/ADP around 10^3 .

Similar calculations of ATP yield and maximum phosphate potential can be made for other systems provided the proton

stoichiometries of the components concerned, and the magnitude of the PMF, are known. Figure 4 summarizes the current view of the PMF-generating reactions during electron transfer from oxygen to NADP in higher plant chloroplasts. For the plant thylakoid F_0F_1 ATP synthase, the most recent structural studies suggest that there are 14 c subunits in its c ring rotor. Since the catalytic F_1 domain is located in the stromal phase where ATP is required, this means that 14 H^+ are required for generation of three ATP at their site of usage. Bacterial F_0F_1 ATP synthases can have c rings with up to 15 subunits. Presumably, these different stoichiometries are tailored to balance an optimal ATP/ADP ratio (which can be driven higher with higher H^+ /ATP coupling ratios) with the net yield of ATP (which decreases as the H^+ /ATP coupling increases).

Transport Systems

A further major insight provided by the chemiosmotic theory is the role played by the PMF in active transport across the chemiosmotic membrane. The lipid membranes themselves are relatively impermeable not only to protons, but also to other charged or hydrophilic ions and metabolites. Transport proteins present in the same membrane are required to catalyze transport across the membrane. Mitchell recognized that the pH and electrical components of the PMF could be used to drive such transport processes provided that the transport proteins have the required properties.

If such transporters result in a net charge change, then the exchange can be driven by the electric field component of the PMF. An example is the adenine nucleotide translocator that catalyzes exchange of ATP (with four negative charges) with ADP (with three negative charges) across the inner mitochondrial membrane (Figure 5). Because the $\Delta\psi$ component of the PMF is negative in the matrix phase, it drives the export of the more negatively charged ATP into the cytoplasm and the ADP into the matrix. This results in a higher ATP/ADP ratio in the cytoplasm than in the mitochondrial matrix.

If the transporter is coupled to a net proton exchange but is overall electroneutral, then the metabolite can be actively

Figure 5 Mitochondrial transport of ADP, ATP, and inorganic phosphate. The mitochondrial inner membrane separates the internal matrix space and the intermembrane space (IMS). The adenine nucleotide translocator catalyzes exchange of one ATP for one ADP. Because ATP^{4-} has one more negative charge than ADP^{3-} , the exchange is electrogenic and will be driven by the electric field in the direction shown. The phosphate transporter catalyzes the transport of $H_2PO_4^-$ with one proton and is electroneutral. It will be driven in the direction shown by the ΔpH component of the PMF.

transported against its concentration gradient, driven by the pH difference across the membrane. An example of this is the phosphate transporter of the inner mitochondrial membrane. This couples transport into the mitochondrial matrix of inorganic phosphate (as H_2PO_4^-) with the co-transport of a proton (or, possibly, with the transport in the opposite direction of a hydroxide). The overall effect is that phosphate transport is electroneutral and is driven by the ΔpH component of the PMF. Bacteria display a wide range of proton-coupled transport systems for active uptake of nutrients. A particularly well-studied example is the lactose transporter of *Escherichia coli*. This co-transporters one H^+ with each lactose so that the lactose can be actively accumulated using both components of the PMF.

Further Aspects

The chemiosmotic theory has provided a sound theoretical basis for understanding of the mechanisms and energetics of energy coupling in respiratory and photosynthetic systems and in membrane-transport processes. New enzymes whose actions contribute to PMF generation, particularly in bacteria, are still being discovered. It is also now known that some bacteria can use a sodium ion gradient in place of a proton gradient to synthesize ATP. The sodium ion gradient can be formed from a proton gradient by the action of transporter that catalyzes electroneutral H^+/Na^+ exchange. However, some bacterial membrane enzymes couple electron transfer or other metabolic reactions to the direct transmembrane movement of sodium ions. Some bacteria, the alkaliphiles, can survive under conditions of extremely high pH; how they manage to do so while maintaining a PMF across their plasma membrane is still not fully understood. Another area of active interest is the finding that animal tissues tend to lose a significant part – up to 50% in some cases – of their proton current as heat. This can occur by slippage within the protonmotive enzymes

themselves, by possible direct proton leak across the lipid membrane at high PMF values and in some systems by the presence of uncoupler proteins that catalyze proton leaks. Besides having a role in thermogenesis in specialized tissues, their other functions are still not fully understood but may include regulation of levels of damaging reactive oxygen species that can form as side products if the PMF rises too high and roles in cellular signaling pathways.

Glossary

Amyloid Fibrillar protein arrays that characteristically and diagnostically bind Congo red or Thioflavin T dyes and show birefringence in polarized light.

Amyloid precursor protein (APP) A large polypeptide with three isoforms. A small, partially intramembrane domain must be proteolytically cleaved to release the 'beta protein'.

APOE-ε4 An allele of the human APOE protein. The presence of two copies of this allele (homozygosity) is associated with an approximately eightfold increased risk of Alzheimer disease.

Beta protein (Aβ) A 40–42 amino acid polypeptide derived by proteolytic cleavage of APP. This polymerizes to form amyloid fibrils in Alzheimer disease.

Dementia Loss of skills related to thinking (cognition) and activities of daily living.

Down syndrome A disorder characterized by three copies of the genetic material from human chromosome 21 (normal

individuals have two copies), usually seen with three (rather than two) copies of the entire chromosome. Characteristic physical changes and a varied spectrum of mental retardation are prominent features.

Fibril A thread-like entity comprised of multiple monomers. Fibrils in Alzheimer disease are highly ordered and have a diameter of ~10 nm.

Plaque A deposit in nerve tissue largely comprised of amyloid (Aβ) fibrils and found in association with dementia.

Presenilin Protease responsible for cleavage of APP to yield Aβ.

Tangle A deposit in nerve cells associated with dementia with Tau protein as a major constituent.

Tau A family of protein isoforms whose normal function(s) involve assembly and stabilization of neurofilaments. Tau proteins are the main constituent of neurofibrillary tangles.

Introduction

Alzheimer disease (AD) is the most commonly recognized form of dementia in the US. Establishing the diagnosis can be difficult because the accepted definition relies on examination of brain tissue and this is usually available only after death. Characteristic features include slowly progressive dementia and diffuse atrophy of the cerebral cortex. It is important, however, to appreciate that the clinical endpoint of dementia may be a final pathway for at least three distinct problems – in addition to AD itself, vascular disease (particularly related to small vessel changes), and Lewy body disease. Thus, dissecting the mechanism(s) of AD alone may be impossible or at least very difficult when based on clinically defined individuals.

Pathologic Changes

Brain tissue from affected individuals shows distinctive changes. Cholinergic neurons are the site(s) of most visible changes and dysfunction. Two types of changes are common – amyloid plaques and neurofibrillary tangles (see Figure 1). Chemical features of these findings have been studied extensively.

Amyloid plaques comprise fibrils ~10 nm in diameter whose main protein constituent is the small protein 40–42 aa, the so-called β protein (see below). They show characteristic apple green birefringence when stained with Congo red or thioflavin T and viewed under polarized light (this feature is common to all types of amyloid fibrils). These fibrils are found extracellularly as well as in microvessels of cerebral tissues and meninges. Within neuronal regions, plaques are generally associated with dystrophic neurons (often containing tangles) as well as reactive glial cells.

Interestingly, nonfibrillar deposits of the β protein may be found prior to the appearance of plaques with their aforementioned fibrillar and tinctorial features. These deposits are generally amorphous and seen in areas (e.g., the cerebellar molecular cortex) not known to be affected in AD. Such diffuse deposits are common in older humans and other primates but are generally not associated with cellular or physiologic evidence of neuronal damage.

Neurofibrillary tangles are intracellular collections of paired filaments derived from tau proteins. These are either straight or paired in helices (so-called paired helical filaments or PHFs). They are not unique to AD but are also found in other disorders of cortical neurons including Pick disease and the parkinsonism-dementia complex of Guam. In other neurodegenerative disorders including progressive supranuclear palsy, corticobasal degeneration and argyrophilic brain disease tangles occur in both neuronal and glial cells.

Understanding biochemical changes responsible for these changes is not yet complete but much important information is known about the proteins involved. The final picture likely results from interaction(s) of multiple factors.

Beta Protein (Aβ)

The most prominent component of amyloid plaques isolated from the brain is a 40–42-amino-acid hydrophobic polypeptide that has been called the beta protein (Aβ). Aβ₄₂ is more likely to form amyloid fibrils than Aβ₄₀. Aβ is a normal secreted polypeptide of unknown function. It can be detected in cerebrospinal fluid and is cleared through vascular pathways. Aβ is derived by specific endoproteolytic cleavage of a much larger

Figure 1 Brain tissue from an individual with Alzheimer disease. The central object is a neuritic plaque. A prominent group of neurofibrillary tangles is at the upper right. Bielschowsky silver stain. Photo courtesy of Dr. Juan Troncoso.

precursor, referred to as the amyloid precursor protein (APP, see **Figure 2**). APP contains a large extracellular domain, a membrane-spanning domain, and a relatively short intracellular domain. There are three APP isoforms of varying length, derived from the same gene by differential splicing. Recent data indicate that APP is important in presynaptic regions for neurotransmission although precise definition of its function(s) has been elusive. $A\beta$ levels in the interstitial fluid of the nervous system are increased with sleep deprivation.

Genetic Relationships with APP

An important correlation is that the gene for APP resides on human chromosome 21 (locus at 21q21) and essentially all individuals with Down syndrome (who have three copies (trisomy) of chromosome 21) develop neuropathic changes of AD by age 40 (considerably earlier than seen otherwise). Individuals with APP gene duplications (independent of trisomy 21) have also been identified and they have pathologic brain changes similar to those seen in AD (these are occasionally limited to association with brain hemorrhage). Over 20 missense mutations have been identified in the APP protein and are associated with a subset of AD known to be familial with a relatively early onset. Most of these mutations flank the $A\beta$ region (**Figure 2**) and may affect proteolysis. Some, however, are within the $A\beta$ sequence itself and likely affect fibril formation. It is important to note that most mutations identified in familial forms of AD are not related to the APP gene.

Proteolysis

The small size of the $A\beta$ protein itself compared with its long APP precursor(s) led to efforts to characterize the responsible proteases. These are known as the β - and γ -secretases; their endoproteolytic cleavage sites are different. The β -secretase cleaves at the N-terminus of what will become the $A\beta$ protein while the γ -secretase cleaves within the transmembrane region and defines the C-terminus of the $A\beta$ molecule (see **Figure 2**). In addition, an α -secretase cleaves within the $A\beta$ protein but outside the transmembrane domain and thus cleavage by the α -secretase prevents formation of the full-length $A\beta$ protein.

Figure 2 Formation of the $A\beta$ protein from the APP precursor involves specific endoprotease cleavages (β - and γ -secretases) as shown. Vertical lines denote membrane boundaries. Note that α -secretase cleavage would interrupt the $A\beta$ sequence. Site(s) of recognized mutations are indicated (x).

Presenilins

Identifying proteins related to AD has been aided by studying families segregating early onset AD but who show no genetic relationship to APP. Presenilin-1 (on chromosome 14) forms part of the aspartyl protease complex serving as the γ -secretase. Presenilin-2 (on chromosome 1) is closely related to presenilin-1. Mutations in presenilin-2 are also associated with familial transmission but are less common. The β -secretase is also an aspartyl protease but no pathologic mutations have yet been associated with it.

Neurophysiologic study indicates that presenilins affect presynaptic nerve termini. Inactivating presenilins alters both neurotransmitter release and induction of long-term potentiation. These effects were not seen when presenilins were inactivated in postsynaptic termini. This is consistent with finding (noted above) that APP is involved in presynaptic physiology.

A recent report (Green et al.) showed that using a γ -secretase modulator (γ -secretase cannot be totally inhibited; doing so suppresses Notch signaling) did not alter the progression of AD dementia.

Amyloid Fibril Formation

The characteristic fibrillar arrays of amyloid are formed from $A\beta$ monomers. $A\beta_{42}$ more readily forms fibrils than $A\beta_{40}$. $A\beta$ fibrils share features common to other types of amyloid including staining with dyes such as Congo red and thioflavin T. The fibrils have a cross- β structure and a diameter of ~ 10 nm and are easily seen by electron microscopy (**Figure 3**). The chemical and biophysical properties of amyloid fibrils are likely central to the pathologic states in which they are found. Fibril assembly, fibril structure, and physiologic consequences of fibrils within and around cells have been studied intensively.

Fibril assembly and growth occur through gradual addition of monomers. Intracerebral injection of $A\beta$ -containing brain extracts from humans with AD or mice transgenic for β -APP led to cerebral β -amyloidosis in APP transgenic mice in a time- and concentration-dependent manner. The findings depended on integrity of the introduced $A\beta$ as well as the status of the recipient mice (i.e., they had to be transgenic for APP). This is consistent with a seed model such as has been proposed for

Figure 3 Electron microscopy of amyloid fibrils from Alzheimer brain. Fibril diameter is ~ 10 nm.

prion-induced neuropathy where a (likely) specific three-dimensional (3-D) structure underlies the inducibility. It also emphasizes the cooperative nature of the process, since non-transgenic mice do not develop the changes. Intercellular transmission of protein aggregates is likely important in pathologic deposits. It is also important to note that injecting brain extracts of misfolded tau proteins (see below) into brains of mice was followed by a spreading pattern of misfolded and aggregated endogenous tau.

Obtaining molecular details of amyloid fibril structure has been difficult. While it has been clear that a cross- β structure is central to fibril formation, stability, and characteristic interaction(s) with planar dyes, all of the atomic interactions are not yet defined. Fibrils are generally too large for crystallographic resolution and their hydration states influence many details. Nevertheless, several features are consistent between studies: (1) N-terminal residues 1–17 of $A\beta_{42}$ are not structured in studies to date, (2) two amino acid stretches (i.e., 18–26 and 31–42) can form β -sheets, (3) two molecules of $A\beta_{42}$ interact to form a protofilament, and (4) the strands in the protofilament are oriented perpendicular to the long axis of the visible fibril.

Lührs et al. proposed a fibril model based on solid-state and quenched hydrogen/deuterium exchange nuclear magnetic resonance analysis. As shown in **Figure 4(a)**, their proposed repeat unit is a bimolecular protofilament. The critical associating region relies on a β -strand-turn- β -strand motif with two intermolecular parallel β -sheets ($\beta 1$ = residues 18–26; $\beta 2$ = residues 31–42). Residues 1–17 are disordered in the structure. Intermolecular side-chain contacts are formed between the odd-numbered residues of $\beta 1$ of the n th molecule and the even-numbered residues of $\beta 2$ of the $(n-1)$ th molecule. As shown, the β strands are oriented perpendicular to the long axis of the fibril. Intermolecular interactions are stabilized by hydrogen bonding and salt bridges. The fibril is polarized with even and odd ends, and growth is toward the odd end. A newly added monomer is less stably connected and, thus, adding yet another monomer provides additional bond energies. This structure implies a sequence-specific, unidirectional, cooperative model for fibril extension consistent with first-order kinetics.

More recently, Schmidt et al. evaluated mass-per-length (MPL) data and electron cryomicroscopy with 3-D reconstruction to assess details of homogeneous fibril populations. They confirmed earlier data suggesting ~ 2.5 $A\beta_{42}$ monomers per protofilament repeat, a number not compatible with the model of Lührs et al. Their model for the protofilament

(**Figure 4(b)**) does not rely on the β -strand-turn- β -strand nucleus but, rather, aligns the C-terminal regions across from each other to form a cross- β structure and leaves the N-terminal domains unstructured (within the resolution of their technology). To address the apparently anomalous MPL figure of 2.5, they propose that additional monomers might periodically decorate the core dimer and/or that peripheral monomers could swap domains with the core dimer at a frequency of ~ 0.5 exogenous monomers per protofilament dimer. Interestingly, their data for $A\beta_{40}$ fibrils indicate that the repeat unit could comprise two of the structures in the $A\beta_{42}$ model as shown.

Although current technology cannot define the precise details, these two models emphasize the dimer as the basic structural unit. The dimers in each model are stabilized by cross- β interactions, as has been noted in all amyloid fibril models. Both models address the possibilities for self-assembly and impressive stability of the fibrils. In most physiologic situations, amyloid fibrils can function as molecular sinks, continually adding monomers, and are very stable in biologic time and environments.

Interestingly, in a mouse model, neurotoxicity appears related to smaller $A\beta_{42}$ oligomers that interfere with synaptic transmission and memory. Structural data on these oligomers are not available. Fibrils (and visible amyloid formation) may accumulate later in the course for these mice. It is important, however, to recall the short life span of the mouse versus the later onset of changes in humans. Mice may not live long enough to develop the full spectrum of pathologic changes, including fibrils.

Tau Proteins

Tau proteins are the primary constituent of the intracellular neurofibrillary tangles. There are six tau isoforms in the brain, all derived from a single gene (see **Figure 5**). Tau proteins are important in assembling and stabilizing microtubules and they form two groups as determined by the number of microtubule-binding repeats (either three or four). The population of isoforms in AD brains appears to be the same as in normal brains.

Formation of filaments from tau proteins is related to serine/threonine phosphorylation of individual tau monomers. This can be extensive; 79 modification sites have been identified in the longest isoform. Phosphorylation can regulate binding of tau to microtubules. Thirty phosphorylated residues have been identified in AD and the proline-directed kinase GSK3 is an important mediator of this modification. Tau filaments are not unique to AD; they are recognized in other neurodegenerative disorders as well (see **Table 1**). Some of these disorders have hyperphosphorylation of distinct tau isoforms; others do not. Pick disease, another neuropathy, is related to a mutation in presenilin-1 that is associated with tau hyperphosphorylation (probably through reduced cadherin binding, reduced PI3K function and increased GSK3 activity) but not AD.

Tau Mutations

Tau mutations (39 known) have been identified in association with specific forms of neurodegenerative disease, classified as tauopathies (see **Table 1**). Two different categories of tau mutations are recognized: (1) mutations affecting splicing and

Figure 4 Proposed Aβ₄₂ protofibril structures. (a, b) Ribbon diagrams of proposed core (aa 17–42) showing intermolecular nature of inter-β-strand interactions. Arrows indicate β strands. Rectangles indicate salt bridges formed by central part of molecules. (c) van der Waals surface and ribbon diagram at the odd end of the Aβ protofibril aa 17–42. Arrow indicates direction of fibril axis (even to odd). (d) Density map of Aβ₄₂ (right) and possible peptide placement (left), based on interpretations shown in (e). (e) Cross sections of 20 nm Aβ₄₀ fibril density maps at two densities. F: 13 nm Aβ₄₀ fibril density map. Note unstructured N-terminal region and β-strand interactions for two Aβ monomers. (2005) 3D structure of Alzheimer's amyloid-β(1–42) fibrils. *Proceedings of the National Academy of Sciences of the United States of America* 102: 17342–17347, copyright (2005) National Academy of Sciences, with permission from PNAS. (d, e) Reproduced from Schmidt M, Sachse C, Richter W, et al. (2009) Comparison of Alzheimer Aβ(1–40) and Aβ(1–42) amyloid fibrils reveals similar protofibril structures. *Proceedings of the National Academy of Sciences of the United States of America* 106: 19813–19818, with permission from PNAS.

Figure 5 Tau protein family showing repeat units and phosphorylation patterns. Red circles indicate microtubule-binding repeats. Heavy lines are constant regions, thin/alternative lines represent alternative splicing.

(2) mutations causing protein changes. Most of the latter affect the microtubule-binding domain. Some mutations enhance filament formation. Mutations within Exon 10 or adjacent introns are associated with higher proportions of tau with four microtubule-binding repeats. This distortion from the normal ratio of tau isoforms apparently enhances the likelihood of neuropathic changes. Different mutations are associated with different filament structures and involve different cell types. Tau proteins may be related to brain development. Learning disabilities have been found in individuals with deletions of 17q21, a region including tau and other genes.

Table 1 Neurodegenerative disorders

Alzheimer disease
ALS/Parkinson–dementia
Argyrophilic grain dementia
Corticobasal degeneration
Creutzfeldt–Jakob disease
Dementia pugilistica
Diffuse neurofibrillary tangles with calcification
Down syndrome
Frontotemporal dementia with parkinsonism (also Pick disease)
Gerstmann–Sträussler disease
Motor neuron disease with neurofibrillary tangles (non-Guamanian)
Myotonic dystrophy
Niemann–Pick disease, type C1
Pantothenate kinase-associated neurodegeneration
Parkinsonism (postencephalitic)
Prion protein cerebral amyloid angiopathy
Progressive subcortical gliosis
Progressive supranuclear palsy
Subacute sclerosing panencephalitis
Tangle-only dementia

Enhanced microscopic tau and filament changes have been reported in cell lines expressing tau mutations that have been crossed with lines expressing APP mutants. By contrast, mice without tau proteins ($\tau^{-/-}$) resisted excitotoxicity associated with $A\beta$ in mice transgenic for the latter.

Risk Factors for AD

Individuals whose AD can be attributed to APP or presenilin mutations account for $\sim 2\%$ of those affected and thus other associations have been sought. The most prominent risk factor for what appears to be sporadic AD is the presence of the $\epsilon 4$ allele of apolipoprotein E (*APOE- $\epsilon 4$*). Homozygosity for this allele imparts an approximately eightfold increase in the likelihood of having AD and of developing changes earlier in life. β -Amyloid fibrils are found more frequently in brains of $\epsilon 4$ homozygotes.

About 25% of individuals with late-onset AD have had a close relative with dementia. A genome-wide association study based on single-nucleotide polymorphism analysis of individuals from 410 AD families confirmed the *APOE- $\epsilon 4$* association and also implicated a locus on 14q31. Although the molecular identity of the locus is not yet known, it appears to affect age of onset of clinical AD changes, thus providing evidence for additional genetic contributions to the neuropathology. The strength of this association is lower than that for *APOE* but it is likely to be a valid risk factor with, probably, additive effect. At least two other loci were identified but must be considered tentatively associated. These studies require very large databases to detect low-level effects although the results support the notion that multiple variation(s) can contribute to AD pathology.

Increasing age is a known risk factor, but it is more difficult to interpret because visible microscopic brain changes may precede clinically evident dementia by several decades. The first visible changes are generally tau filaments but in the neocortex $A\beta$ deposits (not fibrils) are often seen before tau filaments. This is especially prominent in the (rare) individuals

who have underlying APP mutations leading to an excess of $A\beta_{42}$. By contrast, tau mutations are not associated with β -amyloid formation.

Biomarkers and Detection Approaches

Although the histologic changes of plaques and tangles are diagnostic of AD, they are not generally detected during life because tissue is not available. Autopsy studies have shown, however, that such changes can be detected prior to cognitive decline – sometimes 10 or more years earlier. Thus, for both patient care and improved understanding of early events in AD other, noninvasive, approaches to presymptomatic detection have been sought. Serial analysis of high-resolution quantitative magnetic resonance imaging (MRI) images can be used to distinguish AD changes from healthy age-related losses. Positron emission (PET) scanning using the compound ^{11}C -PIB has been used to assess $A\beta$ in the nervous system. When combined with measuring $A\beta_{42}$ levels in the spinal fluid, this has shown reasonable discrimination of AD in early studies. In addition, atrophic brain regions show reduced glucose metabolism by FDG PET.

Measuring $A\beta_{42}$ levels in spinal fluid shows some promise for correlation with amyloid plaques (the presumption is that $A\beta_{42}$ monomers are readily partitioned into fibrils and, hence, monomer levels may be lower elsewhere). Measuring plasma $A\beta_{42}$ levels has not proved useful. Higher levels of both tau and phosphorylated tau proteins in the spinal fluid are seen in individuals with AD than in controls. Sampling spinal fluid is not a simple procedure, however, and doing so is not easily adaptable to large studies. For example, in a large study at 12 centers, measuring spinal fluid levels of $A\beta_{42}$, total tau, and tau phosphorylated at thr 181 could identify incipient AD in individuals with mild cognitive impairment with a sensitivity of 83% but standards were difficult to establish between centers and the approach was not endorsed for routine clinical use. Recently, high blood leptin levels were associated with a reduced incidence of dementia and improved cerebral volume. This finding, if validated, could provide a serum marker for prognosis as well as implicate other pathways in pathogenesis. Other possible biomarkers including proteomics assays have not yet been validated.

Pathophysiology of Alzheimer Changes

It is important to emphasize that all details of Alzheimer neuropathic development are not understood. The histologic changes found in the brains of affected individuals are generally observed late in the course of the progressive dementia, considerably after the cognitive neurologic features have appeared (recall that most studies have been based on autopsy findings). While the visible changes are recognizable, the earlier biochemical events leading to their development are not established. Although specific mutations are recognized in a subset of individuals, they are infrequent and polygenic aspects of AD risk are apparent (see above). Most of the underlying variation(s) likely contribute relatively small amounts to the total risk. In addition, the changes occur over many years (50 or more). Thus, measuring late molecular changes may not identify the primary events and could be misleading. In

addition, animal models such as the mouse cannot be assumed to reflect a simple acceleration of human pathophysiology.

It remains likely that at least some of the brain changes are not unique to what has been called AD. Rather, the classic plaques and tangles may develop relatively late and thus mark common endpoints of multiple pathways of dysfunction (this possibility has been proposed as the so-called tombstone hypothesis).

Several categories of dysfunctional changes have been studied extensively. These categories are not necessarily exclusive.

A β toxicity and mitochondrial integrity

Mitochondria in AD brains are small with fragmented cristae, consistent with excessive mitochondrial fission. Modifying the fission-inducing protein, dynamin-related protein 1 (Drp1) is associated with damage to synapses and neurons. S-Nitrosylation of Drp1 (apparently at Cys644) leads to dimerization and increased guanosine triphosphatase activity, accelerating mitochondrial fragmentation. Physiologically relevant levels of S-NO-Drp1 are found in AD brains. Copper (Cu²⁺) may mediate this reaction and copper levels have been found to be elevated in AD brains (see below). The S-NO-Drp1 appears necessary for nitric-oxide-mediated neuronal damage, and oligomers of A β induce mitochondrial fission and neuronal damage in an NO-mediated manner. Synaptic damage occurs early with loss of dendritic spines. In Drp1 mutants lacking the presumed nitrosylation site (C644A), the A β effect on the spines is blunted. This pathway is consistent with the measured levels of constituents and reactants but does not explain why A β levels are elevated to initiate the process.

Copper

The N-termini of both APP and A β contain high-affinity Cu²⁺-binding domains. The copper-binding site is structurally similar to the site on superoxide dismutase (which has femtomolar copper affinity). A β becomes redox active in excess metal environments. Excess APP or its C-terminal 100 residues can bind copper and thus decrease free copper levels in transgenic mice. Could A β be protective and lessen the effect of copper excess?

Copper levels rise in the aging brain and plaques and Tanzi et al. have proposed that the combination of A β and copper can lead to both H₂O₂ production via a redox mechanism as well as aggregation. Copper and zinc can coordinate A β and precipitate A β at submicromolar concentrations.

Cholesterol

There are epidemiologic associations between high cholesterol levels and AD. Cholesterol itself is a reducing agent for A β -Cu²⁺ and this combination may potentiate formation of reactive oxygen species. This suggests possible synergy between copper and cholesterol. Lowering cholesterol levels with statins can modify vascular risk factors which, as noted above, may contribute to the phenotype of dementia but such treatment is generally begun long before the emergence of neurologic changes late in life. The established relationship to the APOE gene was noted above. A recent study showed that the homozygosity for the isoleucine $\rightarrow$ valine (I405V) change in the cholesterol ester transfer protein was associated with both slower

memory decline and a lower incidence of dementia and AD risk in a prospective cohort study of adults 70 or older without dementia.

Calcium

Regulation of intracellular calcium concentrations has been affected in several model systems. A β has been suggested to form ion channels transporting calcium into neurons. Alternatively, it may distort membranes to produce the same effect. It has also been noted that A β increases calcium influx upon N-methyl-D-aspartate (NMDA) receptor stimulation by glutamate.

Presenilin mutations lead to increased calcium release from endoplasmic reticulum (ER) stores after glutamate stimulation. Another explanation may be that the mutants increase ER calcium levels which subsequently can be released upon cell stimulation. A third possibility is that presenilin mutations interact with other channels – IP₃ and/or ryanodine – to increase calcium release.

Integration

AD pathologic change is a complex process with multiple, independent as well as interacting factors. Lack of neuronal integrity likely leads to apoptosis with mitochondrial fragmentation. In addition, early events can cause an inflammatory response, likely mediated by glial cells, with high local levels of acute-phase proteins and cytokines. Both the aggregates of tau proteins and fibril formation by A β are likely to be relatively late changes in the cascade of neurologic dysfunction. Once begun, however, both relatively disordered aggregates (tau) and highly ordered fibrils (A β) are likely permanent in biologic time. Clarifying the chemistry of the early phases of neuronal dysfunction, which are likely multifactorial, should suggest approaches for minimizing the end-stage findings of advanced AD.

Glossary

Angiogenesis The growth of new vasculature from pre-existing blood vessels.

Chemotaxis Directed migration of leukocytes toward an inflammatory site.

Coreceptor Any of certain chemokine receptors that are used together with CD4 by human immunodeficient virus to enter the target cells.

Desensitization Attenuation of the functional response of chemokine receptors to their ligands following repeated ligand stimulation.

Internalization Translocation of chemokine receptors from the cell membrane to the cytoplasmic compartments.

Metastasis The migration of cancer cells to sites distant from the primary tumor.

Ligands

The ligands that bind and activate chemokine receptors are chemokines or chemoattractant cytokines. Approximately 50 chemokines have been identified, and are classified into four (CXC, CC, C, and CX3C) subfamilies based on their primary amino acid sequences (Table 1). The CXC subfamily has seven members, which have one amino acid (X) interrupting the first two of their four conserved cysteine residues. The CC subfamily has 10 members with no intervening amino acid between the first two of their four cysteine residues. In both the CXC and CC subfamilies, disulfide bonds are formed between the first and third cysteines and between the second and fourth cysteines to establish a stable tertiary structure with the molecular mass of 7–9 kDa. The C subfamily has two members that are 16 kDa in molecular size. The CX3C subfamily has only one member (CX3CL1), which has three intervening amino acids between the N-terminal cysteines, with a molecular mass of 38 kDa, larger than any other known chemokine. Chemokines have two main sites of interaction with their receptors, the flexible N-terminal region and the conformationally rigid loop that follows the second cysteine. Chemokines dock onto receptors by means of the loop region to facilitate the binding of the N-terminal region to the receptor resulting in receptor activation. Chemokines possess heparin-binding capacity at their C-terminal end enabling them to bind to glycosaminoglycans and other negatively charged sugar moieties on cell surfaces and matrix glycoproteins. This property may result in the adsorption of chemokines onto the endothelial cell lining of the blood vessels, connective tissues, and cell matrices. Thus, chemokines immobilized on tissue or matrix surfaces may induce haptotactic migration of target cells.

Structure and Cell Signaling

Chemokine receptors are seven-transmembrane G-protein-coupled receptors composed of approximately 340–370 amino acid residues with 25–80% identity. These receptors

share a common putative structural topology composed of seven hydrophobic transmembrane domains, an N terminus outside the cell surface, three extracellular and three intracellular loops, and a C terminus in the cytoplasmic compartment. The poorly conserved N-terminal domains together with a second binding site in the extracellular loops determine the specificity for ligand binding. The sequence DRYLAIVHA, or a variation of it, in the second intracellular loop and the third intracellular loop is required for G-protein coupling. A cysteine residue in each of the four extracellular domains is required for the disulfide-bond formation that is critical for cell-surface expression. The C terminus of the receptors contains a number of serine and threonine residues that, upon phosphorylation, are involved in signaling and receptor desensitization. A leucine–leucine or isoleucine–leucine motif in the C terminus is required for the receptor internalization (Figure 1). Some chemokine receptors such as CCR2, CCR5, and CXCR4 form homodimers, which may be needed for signal transduction.

Ligand binding to chemokine receptors initiates a cascade of intracellular events (Figure 2). Chemokines bind to the chemokine receptors in the amino terminus resulting in phosphorylation of serine/threonine residues in the carboxyl terminus, conformational changes of the receptor, and activation of the heterotrimeric G-protein complex bound in the intracellular domain of the receptor. Activation leads to the exchange in the α -subunit of the G proteins from the guanosine diphosphate to guanosine triphosphate (GTP)-bound state dissociating the α from the β and γ G-protein subunits. The $G\beta\gamma$ subunits activate phospholipase C (PLC) that hydrolyzes phosphatidylinositol 4,5-bisphosphate [(PIP₂] to produce inositol trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ mediates Ca²⁺ release from the intracellular stores. DAG activates protein kinase C (PKC) resulting in phosphorylation of a number of effector molecules. The activation of isotopes of PLC and hydrolysis of PIP₂ vary among chemokine receptors and from cell type to cell type, accounting for the divergent cellular responses to a given chemokine. Another important signaling pathway of chemokine receptors is the activation of phosphoinositide 3-kinases (PI3Ks), which convert the plasma-membrane lipid PI (4,5)P₂ to

Figure 2 The major intracellular signaling events that are activated by stimulation of a chemokine receptor CXCR2 with the chemokine CXCL8. Stimulation of a chemokine receptor by its ligand results in a conformational change of the receptor and activation of the coupled G proteins. The $G\alpha$ proteins coupled with chemokine receptors are generally the inhibitory $G\alpha$ proteins ($G\alpha_i$). The β - and γ -subunits of the G-protein activate phospholipase C (PLC) which cleaves PIP₂ to produce diacylglycerol (DAG) and inositol triphosphate (IP₃). IP₃ initiates mobilization of the intracellular free Ca^{2+} and DAG activates protein kinase C (PKC). Stimulation also results in activation of nonreceptor tyrosine kinases such as Src, which leads to activation of Dock2/Dock180/Elmo complex and activation of Rac. CXCL8 signaling also regulates several pathways, including mitogen-activated protein kinase (MAPK) pathway, phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) pathway, as well as Rho-signaling pathway. These pathways are required for cytoskeleton dynamics and cell movement. ERK1/2, extracellular signal-regulated kinases 1 and 2; MEK, mitogen-activated protein kinase; Ras and Rho, small G proteins.

phosphatidylinositol-3,4,5-trisphosphate [PI(3,4,5)P₃], resulting in the phosphorylation and activation of the serine-threonine kinase Akt (PKB) by PDK-1 phosphorylation of Ser 308. An additional part of the signals that evoke the motility response involves activation of the Rho GTPase family including Rho A, Rac, and Cdc42. Rac and Cdc42 activate P21-activated kinase, Wiskott-Aldrich syndrome protein or Scar/WASP family Verprolin-homologous protein (WAVE), which, in turn, interact with cofilin or Arp2/3. Rho A mediates cell retraction by activating Rho kinase (ROCK) and Rhotekin, which then activate myosin light chain to form myosin-centered retraction of the uropod. $G\beta\gamma$ subunits also activate nonreceptor tyrosine kinases, Src-family kinases (SFK). In addition to functioning in the cell focal adhesion, SFK was also found to increase Rac activation through Dock180/ELMO1 complex. Chemokines also induce tyrosine phosphorylation of p130 Cas, focal adhesion kinase, and members of the src family in several cell types. Through activation of the Ras, Raf, mitogen-activated protein kinase (MAPK) cascade and through activation of the NF- κ B cascade, transcription factors are activated and gene expression is affected. The signaling pathways of chemokine receptors play a role in cell growth, cell migration, cell survival, and superoxide production. Chemokine receptors also activate signaling pathways independent of G proteins, including JAK/STAT and p38MAPK to regulate gene transcription and cellular migration.

In addition, another class of chemokine receptors that are structurally unable to elicit migration or signaling responses

acts as decoy receptors and scavengers to regulate inflammatory and immune reactions. This subfamily of nonsignaling chemokine receptors includes DARC (Duffy antigen receptor for chemokines), D6, and CCX-CKR (also known as CCRL1).

Desensitization

The ligand-induced activation of chemokine receptors is transient. The functional response of chemokine receptors is rapidly reduced following repeated stimulation by chemokines. This process is called desensitization. Agonist-dependent (homologous) desensitization occurs when a receptor binds chemokine and is phosphorylated by a G-protein receptor-coupled receptor kinase. The phosphorylated receptor recruits β -arrestin, an adaptor protein that uncouples the receptor with G proteins, thus retaining the receptor in a desensitized state, resulting in attenuation in cell excitability (Figure 3). This mechanism plays a major role in determining the duration of leukocyte trafficking, migration, or sequestration in certain situations (see later discussion). Chemokine receptors can also be phosphorylated by a kinase, such as PKC, activated by a different signaling cascade. This is called heterologous desensitization. For example, the chemokine receptor CXCR1 or CXCR2 can be phosphorylated and desensitized through the activation of formyl peptide receptors by the tripeptide formylmethionyl-leucyl-phenylalanine (fMLP). The importance of this phenomenon in inflammation

Figure 3 Homologous desensitization and intracellular trafficking of chemokine receptors. In response to chemokine stimulation, the receptor undergoes desensitization, in which receptor phosphorylation by a G-protein-coupled receptor kinase or another kinase leads to uncoupling of G proteins, binding of β -arrestins and adaptin-2 (AP-2), and subsequent internalization of the receptor through clathrin-coated pits. After pinching off from the membrane, the clathrin-coated vesicles fuse to early endosomes, where the chemokine receptors are dephosphorylated by protein phosphatase 2A and transported to late endosomes and lysosomes for degradation. After removal of the extracellular ligands, the receptors are transported from early endosomes to recycling endosomes to allow a reexpression of receptor at the cell surface. AP2, adaptin 2; CCP, clathrin-coated pit; CCV, clathrin-coated vesicle; EE, early endosome; LE, late endosome; PP2A, protein phosphatase 2A; Rab 4, Rab5, Rab11a, Rab7, small GTPases that regulate receptor trafficking; RE, recycling endosome; SRP, slow recycling pathway; RRP, rapid recycling pathway; LAMP-1, lysosomal-associated membrane protein-1.

and leukocyte trafficking is not completely clear, but the capacity for heterologous desensitization appears to be different among chemokine receptors, suggesting a hierarchy of chemokine/chemokine receptor interactions.

Internalization

After agonist occupancy, chemokine receptors are rapidly translocated from the cell membrane to the cytoplasm, in a process known as internalization. Chemokine receptors generally undergo internalization through clathrin-coated pits, a complex process that involves clathrin and adaptor proteins such as β -arrestins and adaptin-2 (AP-2). β -Arrestin binds to both the carboxyl terminus and third intracellular loop of the chemokine receptor. Studies have shown that AP-2 binds to Leu-Leu, Ile-Leu, and Leu-Ile motifs in the carboxyl terminus of CXCR2 and CXCR4. The association of the adaptor proteins with the chemokine receptor results in recruitment of clathrin and formation of clathrin-coated pits which pinch off from the cell membrane through a dynamin-dependent process to become clathrin-coated vesicles. The clathrin-coated vesicles containing the internalized receptors fuse with early endosomal compartments.

When there is a low pH value in the early endosomes, the receptors become dephosphorylated by a specific serine/threonine protein phosphatase such as protein phosphatase 2A. The dephosphorylated receptors are either transported to recycling endosomes and subsequently re-expressed on the cell surface after removal of the extracellular ligand or delivered to late endosomes and lysosomes for degradation in the continued presence of a high concentration of ligands. The intracellular trafficking processes are regulated by a number of molecules, including the Ras-like GTPases (Rabs) (Figure 3). Rab4 and Rab5 associate with the early endocytic compartment, while Rab11 associates with the perinuclear recycling compartment. Such trafficking may be important for both transmission and termination of the receptor signals and may play an important role in mediating cell chemotaxis (see later discussion).

Multiple Roles

Chemotaxis

Neutrophils, lymphocytes, and other immune cells migrate to the sites of injury and infection. This process, which is called chemotaxis, occurs through the dynamic response of

chemokine receptors expressed on these cells to the gradient concentrations of chemokines produced in the inflammatory sites. Chemokine receptor signaling leading to the establishment of cell polarity, cytoskeletal rearrangement, and interaction with the extracellular matrix plays an essential role in this complex process. In addition, the desensitization and internalization of chemokine receptors play a regulatory role. For example, human immature dendritic cells derived from monocytes express the inflammatory chemokine receptors CXCR1, CCR1, CCR2, CCR5, and CCR7 allowing these cells to follow chemotactic gradients to inflammatory sites. Once there, dendritic cells process antigen and become exposed to the maturation-stimulating cytokines. Maturing dendritic cells express large amounts of chemokines such as CCL3, CCL4, CCL5, CCL8, and CCL10. One consequence of this increased chemokine expression is the downregulation of chemokine receptors on maturing dendritic cells, particularly CCR1 and CCR5, by receptor desensitization and internalization. The second consequence of this upregulation of chemokines is that it strengthens the original chemotactic gradient, further boosting recruitment of immature dendritic cells, monocytes, and lymphocytes.

Human Immunodeficiency Virus Entry

Human immunodeficiency virus (HIV) is the causative agent of acquired immune deficiency syndrome (AIDS). Type 1 HIV (HIV-1) uses chemokine receptor as a coreceptor together with CD4 to enter the CD4-positive (CD4+) target cells. The main cells targeted by HIV-1 are T lymphocytes (T cells), macrophages, and dendritic cells. The chemokine receptors CXCR4 and CCR5 are the major coreceptors for T-cell line-tropic and macrophage-tropic HIV-1 strains, respectively, although many other chemokine and orphan receptors have been identified as potential coreceptors for HIV-1. The fusion of the viral envelope and the lymphocyte occurs when the envelope glycoprotein on the surface of virus particles (comprising a trimer of three gp120 and three transmembrane gp41 molecules) binds to CD4 triggering a structural change exposing a binding site for a coreceptor. Further structural rearrangements are initiated when the coreceptor is bound. These changes occur predominantly in gp41 and are sufficient to trigger fusion of viral and cellular membranes and entry of the virion core into the cytoplasm.

Angiogenesis

Angiogenesis is the formation of new blood vessels from pre-existing microvasculature. This biological process is critical to both physiological and pathological processes such as wound healing and tumor growth. Angiogenesis is regulated by an opposing balance of angiogenic and angiostatic factors. The CXC chemokines are a family of cytokines unique in their ability to behave in a disparate manner in the regulation of angiogenesis. The N terminus of the majority of the CXC chemokines contains three amino acid residues (Glu-Leu-Arg; the ELR motif). This motif, in general, determines whether these chemokines promote angiogenesis. Members that

contain the ELR motif (ELR+), such as CXCL1, CXCL2, and CXCL8, are potent promoters of angiogenesis. A novel link between CXCL1 and prostaglandin E2 has been shown to promote angiogenesis in a mouse model for colon cancer. By contrast, members that are inducible by interferons and lack the ELR motif (ELR-), such as CXCL10, are potent inhibitors of angiogenesis (angiostatic chemokines). ELR+ CXC chemokines bind to CXCR2 and CXCR1, whereas non-ELR- CXC chemokines bind to CXCR3, CXCR4, CXCR5, and CXCR6. CXCL12/CXCR4 axis has been shown to recruit and retain 'recruited bone marrow-derived circulating cells' and support neovascularization of the tumor.

Tumor Growth and Metastasis

Many cancer cells such as melanomas express a number of chemokines, including CXCL8, CXCL1-3, CCL5, and CCL2, which have been implicated in tumor growth and progression. Recent studies have demonstrated organ-specific patterns of melanoma metastasis that correlate with their expression of specific chemokine receptors, including CXCR4, CCR7, CCR9, and CCR10. The chemokine receptors CXCR4 and CXCR7 are also found on breast cancer cells and their ligands are highly expressed at sites associated with breast cancer metastases. Other models in which CXCR4 has been suggested to play a role in metastasis are ovarian, prostate, and lung cancers. In addition, studies have shown that decreased expression of Duffy and D6 decoy receptors in breast cancer inversely correlate with lymph node metastases and increased survival rates. Increased levels of CCL2 expression in breast cancer have been associated with increased levels of tumor-associated macrophages, correlating with invasive phenotype and poor prognosis. It is postulated that chemokine receptors and their ligand pairs play a role in the migration of tumor cells from their primary site via the circulation to the preferential sites of metastases.

Central Nervous System

In addition to their well-established role in the immune system, chemokines and chemokine receptors are involved in the development, homeostasis, synaptic transmission, and neuroinflammation of the central nervous system (CNS). In the CNS, chemokines function as neuromodulators by coordinating the paracrine communication between the neurons, glial and immune cells acting through their chemokine receptors present on these cells.

Chemokine receptors such as CXCR2, CXCR4, CXCR7, CCR1, and CCR5 and chemokine CXCL12 are constitutively expressed in both developing and adult brain. Other chemokines and chemokine receptors are induced depending on the pathological context. Expression of the chemokine CCL21 is induced in neurons around the ischemic brain lesions and spinal cord injury model. Interestingly, CCL21 activates microglia through CXCR3 and not through CCR7. Chemokines and their receptors target the neurons to their destination by modulating migration, differentiation, and proliferation of neuronal and glial cells. The chemokine receptor CXCR4 and its

chemokine ligand CXCL12 play a role in neuronal migration to hippocampus, cerebellum, axonal path finding. CXCL12 antagonizes the axon repellent properties of slit/robo in a retinal neuron model. Perturbation of CXCL12/CXCR4 signaling causes premature cortical plate invasion by GABAergic cortical interneurons leading to positional defects in postnatal cortex. The chemokine receptor CXCR7 coordinates the CXCR4-driven neuronal migration by shaping the extraneuronal CXCL12 gradient. Apart from neuronal homeostasis, chemokines are involved in neuroinflammation as mediators of leukocyte infiltration and glial-cell activation. Their overexpression has been implicated in several neurological disorders, such as multiple sclerosis, trauma, stroke, late stages of Alzheimer's disease, chronic pain, tumor progression, and AIDS-associated dementia. Chemokine receptor antagonists seem to be beneficial in CNS disorders where there is an overexpression of the chemokines or overactivation of the chemokine receptors. In addition, several chemokines and their receptors are implicated in neuroprotection. The employment of chemokines CXCL1, CXCL8, CXCL12, and CX3CL1 are implicated in neuroprotection in different models of neurotoxicity such as gp120, N-methyl-D-aspartate-induced excitotoxicity, and early stages of Alzheimer's disease.

Glossary

Aerobic respiration Movement of electrons from a growth-supporting substrate, through an electron transport chain to dioxygen as the terminal electron acceptor.

Anaerobic respiration Respiration utilizing a terminal electron acceptor other than dioxygen.

Autotrophy A mode of bacterial growth in which carbon dioxide is the source of all or most of the carbon for biosynthesis. These bacteria are autotrophic. Autotrophy contrasts with heterotrophy, a mode of growth where reduced carbon compounds can provide all carbon for biosynthesis.

Chemolithotrophy A mode of bacterial growth in which the reductive substrate for energy generation and for biosynthesis is an inorganic or a single-carbon compound. These bacteria are chemolithotrophic. Chemolithotrophy contrasts with organotrophy or phototrophy in which the energy generation occurs by the oxidation of complex organic molecules or absorption of light, respectively.

Energy substrate A compound that supplies the energy necessary to: (1) drive the phosphorylation of adenosine

diphosphate (ADP) to adenosine triphosphate (ATP) and (2) generate a membrane potential.

Growth-supporting reductant A compound whose oxidation can be coupled biologically to the conservation of energy in forms of general use to cellular activities: as an electrochemical gradient, as a phosphate anhydride bond in ATP, or as the low-potential reductant, reduced nicotinamide adenine dinucleotide.

Methylotrophy A mode of bacterial growth in which the reductive substrate for energy generation and for biosynthesis as well as the carbon source is a single-carbon compound.

Oxic environment An environment containing dioxygen (O_2). The word aerobic is also used. Oxic contrasts with anoxic (or anaerobic) which applies to environments in which oxygen is absent.

Redox Oxidation–reduction reaction.

Terminal electron acceptor (TEA) A compound whose reduction can be coupled to the stoichiometric oxidation of the growth-supporting reductant and conservation of energy in cells.

The chemolithotrophic bacteria and archaea are defined by their ability to oxidize inorganic atoms or molecules as a growth-supporting reductant (Table 1). The enzymes catalyzing these oxidations are unique in nature. A metabolically related group, the methylotrophic microorganisms, utilizes one-carbon compounds (C_1) as a growth-supporting reductant and sole carbon source. The enzymes catalyzing the C_1 oxidations are similar to those of the chemolithotrophs that are described here. The various overall growth-supporting reactions are tabulated here with the reductive and oxidative half-reactions of intermediate enzymatic steps. These half-reactions are steps in the cycling of carbon, hydrogen, nitrogen, sulfur, and metals in nature and have played significant roles in the geochemical history of earth.

Oxidation of the growth-supporting reductant initiates a chain of oxidation–reduction electron-transfer reactions ending with reduction of a terminal electron acceptor (TEA) such as dioxygen. This results in the generation of a membrane potential that can provide the driving force for synthesis of high-energy compounds such as adenosine triphosphate (ATP). Alternatively, the electrons from the growth-supporting substrate reduce compounds such as nicotinamide adenine dinucleotide ($NADH + H^+$), which are employed as universal electron donors in reductive biosynthetic reactions.

Universal Bioenergetic Reactions; Oxidation of the Growth-Supporting Substrate Drives Synthesis of ATP

All organisms require a source of energy to drive biosynthesis, mechanical work, and translocation of molecules across a membrane against a gradient. In cells, potential energy is commonly stored in three basic forms: (1) transmembrane electrochemical potential, (2) the potential-free energy of hydrolysis of a phosphate anhydride bond of ATP, and (3) the low redox potential of the reaction $NAD^+ + 2e^- + 2H \leftrightarrow NADH + H^+$.

The hydrolysis of the terminal phosphoric anhydride bond of ATP can drive an otherwise thermodynamically unfavorable reaction when an enzyme functionally couples the two reactions. The re-phosphorylation of the resulting adenosine diphosphate (ADP) is catalyzed by ATP synthase, an enzyme that is able to use the potential energy of a steady-state transmembrane electrochemical gradient; as protons are relayed across the membrane through the ATP synthase, the enzyme couples ADP and phosphate (P_i) to ATP. In turn, maintenance of the proton electrochemical gradient requires the continuous turnover of the low potential half-reaction (the oxidation of the growth-supporting reducing substrate). The continuation of the latter oxidative reaction is dependent on a high-potential

Table 1 Reductive reactions employed by bacteria

Half-reaction	Sample enzyme/process	Sample species
Aerobic conditions		
a. $O_2 + 4e^- + 4H^+ \rightarrow 2H_2O$	Cytochrome <i>c</i> oxidase	<i>Azotobacter vinlandii</i>
Anaerobic conditions		
b. $NO_3^- + 2e^- + 2H^+ \rightarrow NO_2^- + H_2O$	Periplasmic nitrate reductase	<i>Paracoccus denitrificans</i>
c. $NO_2^- + e^- + 2H^+ \rightarrow NO + H_2O$	Cytochrome <i>cd</i> nitrite reductase	<i>Paracoccus denitrificans</i>
d. $NO_2^- + 6e^- + 8H^+ \rightarrow NH_4^+ + 2H_2O$	Pentaheme nitrite reductase	<i>Campylobacter jejuni</i>
e. $2NO + 2e^- + 2H^+ \rightarrow N_2O + H_2O$	Cytochrome <i>c</i> -dependent nitric oxide reductase	<i>Paracoccus denitrificans</i>
f. $N_2O + 2e^- + 2H^+ \rightarrow N_2 + H_2O$	Nitrous oxide reductase	<i>Paracoccus denitrificans</i>
g. $2H^+ + 2e^- \rightarrow H_2$	Hydrogenase	<i>Rhodospirillum rubrum</i>
h. $C_4H_4O_4 + 2e^- + 2H^+ \rightarrow C_4H_6O_4$	Fumarate reductase	<i>Escherichia coli</i>
i. $CO_2 + 8e^- + 8H^+ \rightarrow CH_4 + 2H_2O$	Methanogenesis	<i>Methanosarcina barkeri</i>
j. $2CO_2 + 8e^- + 8H^+ \rightarrow CH_3COOH + 2H_2O$	Acetogenesis	<i>Acetobacterium woodii</i>
k. $SO_4^{2-} \rightarrow SO_3^{2-} \rightarrow S_4O_6^{2-} \rightarrow S_2O_3^{2-} \rightarrow S^0 \rightarrow S^2$	Sulfate reduction	<i>Desulfovibrio desulfuricans</i>
l. $Fe^{3+} + e^- \rightarrow Fe^{2+}$	Iron reductase	<i>Shewanella putrefaciens</i>
m. $Hg^{2+} + 2e^- \rightarrow Hg^0$	Mercury reductase	<i>Shewanella oneidensis</i>
n. $Mn^{4+} + e^- \rightarrow Mn^{2+}$	Manganese reductase	<i>Shewanella putrefaciens</i>
o. $U^{6+} + 2e^- \rightarrow U^{4+}$	Uranium reduction	<i>Shewanella putrefaciens</i>
p. $Cr(VI) + 2e^- \rightarrow Cr(IV)$	Chromium/uranium oxidoreductase	<i>Desulfovibrio desulfuricans</i>
q. $Cs(VI) + 3e^- \rightarrow Cs(III)$	Cesium reductase	<i>Shewanella oneidensis</i>
r. $Se(VI) + 4e^- \rightarrow Se(0)$	Selenium reductase	<i>Shewanella oneidensis</i>
s. $Tc(VI) + e^- \rightarrow Tc(V)$	Technetium reductase	<i>Shewanella oneidensis</i>
t. $As(V) + 2e^- \rightarrow As(III)$	Arsenate reductase	<i>Desulfovibrio</i>
u. $(CH_3)_3NO + 2e^- + 2H^+ \rightarrow (CH_3)_3N + H_2O$	Trimethylamine reductase	<i>Shewanella putrefaciens</i>
v. $(CH_3)_2SO + 2e^- + 2H^+ \rightarrow (CH_3)_2S + H_2O$	Dimethylsulfoxide reductase	<i>Shewanella putrefaciens</i>

The substrates of these reactions are terminal electron acceptors.

Figure 1 General scheme for oxidation of growth supporting substrate X, listed in **Tables 3–6**, generation of a proton gradient, and phosphorylation of ADP + Pi to ATP in chemolithotrophic and methylotrophic microorganisms. Abbreviations: ATPase, ATP synthase; NDH, NADH dehydrogenase; and TEA, terminal electron acceptor.

half-reaction by which a growth-supporting oxidant substrate, TEA, is reduced by electrons originating from the growth-supporting reductant (**Figure 1**). A series of metallo-enzymes, electron transfer proteins, and quinones are oriented topologically in the cytoplasmic membrane so as to force the net vectorial transfer of protons from the cytosol to the external or extracytoplasmic side of the membrane, resulting in an electrochemical gradient.

To summarize, the potential energy of oxidation of growth substrate by the growth TEA is recovered by coupling these redox reactions to the vectorial transfer of protons from the cytosol to the extracytoplasmic side of the cell membrane and the energy stored in the form of a membrane electrochemical potential. The energy stored in the electrochemical gradient

can then be used to drive enzyme-catalyzed reactions such as the phosphorylation of ADP to ATP.

The Variety of TEAs Used by Bacteria

Many bacteria are able to use one or more of the half-reactions shown in **Table 1** as an electron sink supporting the continuity of the energy-generating reactions; these substrate molecules are TEAs. Because of its high redox potential and resulting high potential difference with the growth-supporting half-reaction, half-reaction 2a is favored by bacteria if oxygen is available. The other TEAs are used when oxygen is absent (i.e., in anoxic or anaerobic rather than oxic or aerobic environments). Note that the reduction of protons in half-reaction g requires an especially low-potential reductant. Line i is a multi-step process carried out by the methanogenic bacteria. In line k, each step involves two electrons. The sulfur-reducing bacteria vary in the steps that they are able to use.

Reductant for Biosynthesis

Biosynthetic reactions often require an electron- or hydride-donor reaction with a low enough potential to drive reductive reactions. The electron donor molecule is often the reduced form of NADH. Hence, a second role of the growth-supporting reductant is the reduction of NAD^+ ($NAD^+ + 2e^- + H^+ \rightarrow NADH$) (see **Figures 1** and **2**). In the chemoautotrophs, $NADPH + H^+$ is used as reductant for biosynthetic reactions.

Figure 2 Catalysis of the oxidation of ammonia to nitrite coupled to generation of ATP and NADH in the chemolithotrophic bacterium, *Nitrosomonas europaea*. The four enzymes in the center of the figure create a proton gradient, which is employed by the enzymes on the left and right to drive production of NADH and ATP, respectively. Electrons from hydroxylamine oxidoreductase are relayed by heme-containing electron-transferring proteins, cytochromes in which Fe cycles between Fe^{2+} and Fe^{3+} , to reduce a quinone to a quinol (QH_2). The quinol is reoxidized either by ammonia monooxygenase or by an electron-transfer chain including a proton-pumping ubiquinol–cytochrome *c* reductase, a cytochrome *c*, and a proton-pumping cytochrome oxidase. The proton-pumping NADH-dehydrogenase functions in reverse to form NADH as shown in the figure. ATP synthase catalyzes the proton gradient-driven phosphorylation of ADP. The periplasm is the region outside the cell membrane; the cytoplasm is inside the cell membrane. The membrane itself is impermeable to protons.

Table 2 Classification of microbes based on reductant for biosynthesis and energy-driving ATP-forming reactions and by carbon source

Physiological type	Common name	Carbon source	Electron source	Energy source
Term				
Photo-				Light
Chemo-				Chemical
Autotroph		CO_2		
Organotroph		Organic	Organic	
Lithotroph			Inorganic	
Types				
Photolithoautotroph	Photosynthetic	CO_2	Inorganic	Light
Photoorganotroph	Photoheterotroph	Organic	Organic	Light
Chemolithoautotroph	Chemolithotroph/chemoautotroph	CO_2	Inorganic	Inorganic
Chemoorganotroph	Heterotroph	Organic	Organic	Organic

Categories of Growth of Bacteria and Archaea Based on the Nature of the Growth-Supporting Reductant

Organisms for which the growth-supporting reductant is a reduced multi-carbon molecule such as glucose are called chemoorganotrophs (Table 2). The sum of many reactions, including dehydrogenations, in the pathway of aerobic glucose oxidation is

Organisms defined as phototrophs are able to photo-chemically activate an internal chlorophyll to a lower potential reductant. Re-oxidation of the latter drives the creation of the proton electrochemical gradient and then synthesis of ATP. Electrons can either be recycled back to the center of

photochemical reduction resulting in a continuous steady-state gradient and ATP production or can be used to reduce NAD^+ and end up in fixed carbon molecules. Therefore, phototrophs require an external electron source, such as H_2O , to support biosynthesis. Phototrophic bacteria can use either organic or inorganic (e.g., H_2 or H_2S) reductants and are called photo-organotrophs or photolithotrophs, respectively.

Chemolithotrophy

Microorganisms that are specialized to use inorganic compounds as their growth-supporting reductant and energy source are called chemolithotrophs. Bacteria that are able to grow only in this manner are obligate chemolithotrophs; facultative chemolithotrophs have the enzymes necessary for chemoorganotrophic, photoorganotrophic, photolithotrophic, or chemolithotrophic growth. The reducing half-reactions of the major chemolithotrophic growth-supporting substrates are listed in Tables 3–7. In many chemolithotrophic bacteria, the oxidation of the growth-supporting reductant is coupled to reduction of oxygen (Table 1(a)). The overall reactions supporting ATP synthesis and NAD^+ -reduction in aerobic bacteria, which oxidize ammonia, methane, sulfur, hydrogen, or ferric ion with dioxygen as TEA, are as follows:

Bacteria which use a growth-substrate half-reaction with a sufficiently low redox potential can also grow anaerobically

Table 3 Oxidation of the growth-supporting reductant in the nitrifying bacteria

Half-reaction	Sample enzyme/process	Sample species
Aerobic ammonia oxidizing bacteria

using TEAs other than oxygen as shown in the following examples:

Examples of Half-Reactions of the Growth-Supporting Reductant in the Chemolithotrophic Bacteria

As illustrated below, the origin of the O atom in the oxide product in some cases is O_2 and in some cases is H_2O .

Nitrifying Bacteria (Oxidation of Ammonia to Nitrite and Then Nitrate)

The half-reactions of the nitrifying bacteria make up the oxidative arm of the nitrogen cycle (Table 3). The recently discovered chemolithotrophic anaerobic ammonia oxidizing (ANAMOX) bacteria generate energy in a series of reactions involving ammonia and nitrite with hydrazine as an intermediate and dinitrogen as the end product.

Methane-Oxidizing Bacteria

Both aerobic and anaerobic oxidation of methane by the methanotrophic bacteria (Table 4(a, b)) involves an electron-consuming methane monooxygenase (Table 4(a)(i)) and successive methanol-, formaldehyde-, and formate-dehydrogenases

(Table 4(a)(ii)–(iv)). The conversion of carbonic acid to CO₂ can be spontaneous or enzyme-catalyzed (Table 4(a)(v)). Methylotrophs are bacteria which grow on C₁-compounds, including methane, methanol, formaldehyde, formic acid, methyl amines, dichloromethane, and methane sulfonic acid.

Hydrogen and Carbon Monoxide-Oxidizing Bacteria

Hydrogenase of hydrogen-oxidizing bacteria oxidizes hydrogen to protons and electrons (Table 5(a)). In the carboxydo-bacteria, carbon monoxide dehydrogenase catalyzes the net extraction of two electrons and two protons to produce carbon dioxide from carbon monoxide and water (Table 5(b)).

Sulfur-Oxidizing Bacteria

Depending on the specific bacterium, oxidation of a variety of reduced sulfur compounds is used to support growth. Some examples of the half-reactions are shown in Table 6(a–d). Some bacteria utilize the adenosine phosphosulfate (APS)

pathway for synthesis of ATP coupled to the oxidation of sulfite and represent a rare example of substrate level phosphorylation couple in chemolithotrophic bacteria (Table 6(c)).

Metal-Oxidizing Bacteria

The half-reactions shown in Table 7(a–g) are carried out by a variety of bacteria, chemolithotrophically or photolithotrophically, under both aerobic and anaerobic conditions. For example, a metallo-enzyme catalyzes the oxidation of ferrous iron to ferric ion, which hydrolyzes to form an orange precipitate of ferric hydroxides:

Mechanisms of Energy Transduction and ATP Synthesis Somewhat Specific to Chemolithotrophs

Generation of the Electrochemical Gradient and ATP Synthesis

Some generalizations regarding location of the enzymes catalyzing the oxidation of substrate, generation of a proton gradient, and synthesis of ATP are illustrated in the oxidation of ammonia to nitrite by the nitrifying bacterium *Nitrosomonas*, an obligate chemolithoautotroph (Figure 2). Although ammonia is the substrate required for growth, it is the oxidation of hydroxylamine that generates low potential electrons for energy conversion and reductive biosynthetic reactions. Four electrons are transferred from hydroxylamine oxidoreductase (Table 3(a) (ii)) to an electron-transfer chain made up of

two heme-containing proteins (cytochromes) to two quinone molecules in the membrane. Two electrons from the reoxidation of one quinol are utilized by ammonia monooxygenase to regenerate a molecule of hydroxylamine, that is, to re-prime the pump. The two electrons (per hydroxylamine oxidized) from the second quinol may reduce dioxygen in a pathway which involves the two membrane enzymes, ubiquinol cytochrome *c* reductase and cytochrome *c* oxidase, each of which couples the reaction to the transport of protons against a gradient to the outside (the periplasm of the bacterial cell). In this way, a steady-state electrochemical potential (outside positive) is maintained across the membrane and drives ATP synthesis.

Substrate-Level Phosphorylation of ADP

In some chemolithotrophic sulfite-oxidizing bacteria, the net phosphorylation of ADP occurs by a substrate-level process, which is independent of the membrane electrochemical gradient (Table 5(c) (iii)). The key reaction involves the simultaneous dehydrogenation of sulfite and reaction with adenosine monophosphate (AMP) to form the anhydride of phosphoric and sulfuric groups in the product, APS:

Phosphate can then displace sulfate to form ADP and the subsequent dismutation of two molecules of ADP provides an ATP:

Periplasmic Release and Cytoplasmic Utilization of Protons in Chemolithotrophic Reactions

In the reducing half-reactions of the major chemolithotrophic growth-supporting reductants (Tables 3–7), the energetically fruitful reactions are, in effect, dehydrogenases where the products are free protons and electrons are transferred to an enzyme redox center which is often a metal such as Fe or Cu.

The protons originate from the substrate (in the oxidation of ethanol, formaldehyde, H_2 , N_2H_4 , H_2S), H_2O (in the oxidation of CO, nitrite, S^0 , SO_3^{2-}), or both (in the oxidation of NH_2OH). In all cases where location of the enzyme has been determined, the proton-yielding reactions are found in the periplasm or periplasmic face of the membrane and thus contribute to maintenance of the positive charge on the outer side of the membrane. Correspondingly, almost all TEA reactions (Table 1) that consume protons are located on the cytoplasmic side of the membrane, thus contributing to the maintenance of the negative charge on that side. This is illustrated in the location of hydroxylamine dehydrogenation and oxygen reduction in *Nitrosomonas* (Figure 2).

Production of NADH by Chemolithotrophic Bacteria

With many chemolithotrophs, the potential of the half-reaction that drives metabolism (in the case of *Nitrosomonas*, the dehydrogenation of hydroxylamine) is apparently not low enough to reduce NAD^+ directly. Thus, chemoautotrophs must drive electrons in the reverse direction to reduce NAD^+ to $\text{NADH} + \text{H}^+$ in a process called reverse electron transport. The final reaction in this process is catalyzed by the NADH dehydrogenase. In chemoorganotrophs, the NADH dehydrogenase oxidizes $\text{NADH} + \text{H}^+$ to NAD^+ , reduces quinone, and pumps protons to the outside of the cell. However, in the case of *Nitrosomonas* (Figure 2) and other chemolithotrophs, the reaction runs in the reverse direction to form NADH. This process is not needed in bacteria, such as the hydrogen oxidizers, where the growth-supporting potential of the reductive half reaction ($\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$) has a low enough value that NAD^+ is reduced directly.

Carbon Source for Chemolithotrophic Bacteria

The carbon source for most chemolithotrophic bacteria is CO_2 . This mode of growth is called autotrophic, that is, the organisms are chemolithoautotrophs (Table 2). Most chemolithotrophs are obligate autotrophs, meaning that they can only grow having synthesized all or most of their reduced carbon compounds from CO_2 . This contrasts with heterotrophic organisms, which can fulfill all their need for carbon compounds with previously fixed carbons such as sugars. Facultative autotrophs are able to alter their content of biosynthetic enzymes to catalyze either the autotrophic or heterotrophic mode of life. The most common pathway of carbon dioxide fixation in the chemolithoautotrophs is the Calvin cycle, starting with the reaction of ribulose bis-phosphate carboxylase, which catalyzes the following reaction:

Considering the reduction of 3-phosphoglycerate and the regeneration of ribulose 1,5-bis-phosphate in the Calvin cycle, approximately 12 molecules of NADH and 18 of ATP are required per hexose synthesized from CO_2 . Remarkably, the obligate chemolithoautotrophs contain the enzymes for biosynthesis of all cellular constituents. Further, they have genes for enzymes for the uptake, metabolism, and incorporation of carbon from extremely few carbon compounds other than

CO₂. This was illustrated by analysis of the genes present and absent in the genome of *Nitrosomonas*.

Growth Yields of Chemolithoautotrophs

Since the reduction potential of the half-reactions utilized by the chemolithotrophs often has a low value, the energy yield from the overall growth reaction is lower than commonly observed with organotrophs. Given the required expenditure of energy required to drive the synthesis of ATP and the reduction of NAD⁺, which are then used in biosynthetic reactions, the yield of biomass per mole of substrate oxidized is usually much lower in the chemolithoautotrophs than with heterotrophic organotrophs. Profiting from their unique catalytic capabilities, chemolithotrophs grow slowly and live frugally with a highly selective diet of a thin low-calorie soup of inorganic compounds or small carbon molecules.

Ecology

The chemolithotrophs and methylotrophs represent the oxidative segment of the biological cycles of inorganic compounds such as hydrogen, nitrogen, sulfur, metal ions, and carbon. The vast majority of these steps occurs aerobically. These reactions and the bacterial reduction of inorganic TEAs have played significant parts in the geochemical history of carbon, nitrogen, oxygen, sulfur, and metals on earth.

Most of the reduced substrates for chemolithotrophs are generated by the terminal electron accepting reactions of anaerobic organisms (Table 1). For example, hydrogen from reduction of protons (Table 1(g)) by organotrophic bacteria in cattle rumen is oxidized (Table 5(a)) by chemolithotrophic hydrogen-oxidizing bacteria using the conversion of carbon dioxide to methane as the TEA half-reaction (Table 1(j)). Methane released from ruminants finds its way to an oxic (aerobic) environment where it is oxidized by the methanotrophic bacteria (Table 4(a)). The chemolithotrophs and the anaerobes are sometimes found at oxic/anoxic (aerobic/anaerobic) interfaces where the respective oxidative and reductive reactions provide a cycle to the advantage of both types of organism. There are many examples of economically significant effects of chemolithotrophic activity. For example, reduction of sulfuric acid by the sulfur-oxidizing bacteria facilitates corrosion of metals and has been used to extract metals in commercial mining processes.

Glossary

Chemokine A family of structurally related 70–90-amino-acid-long glycoproteins that exhibit potent chemotactic and stimulatory properties on leukocytes.

Complement system A series of 30 components that include proteolytic pro-enzymes, nonenzymatic components that form functional complexes, regulators, and receptors. The proteolytic pro-enzymes become sequentially activated. C5a and C3a are terminal nonenzymatic cleavage products.

G protein A protein that binds and is regulated by guanine nucleotides. Heterotrimeric members of this family couple to GPCRs. Low-molecular-weight monomeric members of the family are activated downstream of heterotrimeric G proteins.

G-protein-coupled receptor (GPCR) Transmembrane receptor containing seven membrane-spanning helices that activates cells through coupling to heterotrimeric G proteins.

A critical aspect in the normal function of many cell types is their ability to migrate in response to soluble ligands or chemoattractants. Directional migration, where the cell seeks out the highest concentration of chemoattractant, is referred to as chemotaxis. This is of paramount importance in the immune system where a large collection of G-protein-coupled receptors (GPCRs) exists to coordinate the complex interactions of immune cells. These receptors can be divided into two families, the chemotactic or chemoattractant GPCRs that respond to a wide variety of endogenous as well as exogenous ligands and the chemokine GPCRs that respond to the structurally conserved family of endogenous peptide chemokines. The chemotactic GPCRs respond to ligands as varied as oligopeptides, such as bacterially derived N-formylated peptides; proteins, such as complement components; and lipids, such as leukotrienes and platelet-activating factor.

Leukocytes and the Immune System

The immune system is responsible for numerous activities in the body including defense against pathogens (bacterial, viral, and parasitic), removal of dead and cancerous cells as well as the rejection of foreign cells. Leukocytes, or white blood cells, which represent the principal cells of the immune system, are produced as progenitor cells in the bone marrow and mature in various sites throughout the body, including the spleen, thymus, and lymph nodes. Leukocytes can be divided into five broad categories: neutrophils (highly mobile phagocytic cells), basophils (allergy mediators through histamine release), eosinophils (parasitic killing and allergy), lymphocytes (B cells that produce antibodies and T cells that affect cell-mediated immunity), and monocytes/macrophages (tissue-specific phagocytic cells). These cells differentially participate in two types of immune responses: innate immunity, an inherent and rapid response of neutrophils, macrophages, and natural killer lymphocytes to foreign materials; and acquired immunity, a selective trained response involving lymphocytes requiring prior exposure to an agent. An additional noncellular defensive mechanism, the complement system consisting of at least 20–30 distinct serum proteins,

destroys foreign cells through membrane lysis of antibody-targeted cells. Two of the smaller bioactive fragments released by proteolysis from the C3 and C5 components, C3a and C5a, are known as anaphylatoxins and play a major role in inflammation. Immune cells for the most part circulate in the vascular and lymphatic systems, although tissue resident cells such as macrophages are essential to proper immune function. In almost any immune response, however, leukocytes must migrate to the site of damage/infection from the blood. This is a complex multistep process involving inflammatory mediators (such as histamine) that induce vasodilation and increased vascular permeability, activation of adhesion molecules on capillary lining endothelial cells to slow leukocytes, and release of chemoattractants to activate leukocytes resulting in firm adhesion to endothelial cells. The concentration gradients of chemoattractants induce the leukocyte to transverse the endothelium and migrate through the tissue to the peak concentration of chemoattractant at the site of inflammation or infection. Having arrived at this site, neutrophils, for example, phagocytose bacteria, generate superoxide radicals and release granules containing degradative proteases. Most of these responses are initiated and regulated by a family of cell surface receptors that bind inflammatory mediators.

Receptors

The largest family of proteins in the human genome is the GPCR superfamily consisting of at least 600 members. GPCRs possess a highly conserved structure, consisting of seven transmembrane segments with the amino terminus on the cell exterior and the carboxy terminus in the cytoplasm. The chemoattractant family of receptors consists of proteins with 350 amino acids. The transmembrane regions consist primarily of α -helices arranged in a bundle. Despite this conserved structure, there is substantial sequence diversity between members of this receptor family. Binding of small ligands, such as chemotactic peptides, occurs deep within the receptor in the plane of the membrane. Ligand binding and receptor activation result in conformational changes that activate heterotrimeric

G proteins, which further stimulate a wide variety of effector proteins. Following activation, GPCRs undergo phosphorylation, resulting in desensitization and internalization, which in turn can lead to receptor degradation or recycling back to the cell surface.

Chemotactic Peptide Receptors

Though identified as a neutrophil receptor for N-formylated peptides in the 1970s, it was not until 1990 that the N-formyl peptide receptor (FPR) gene was isolated, representing the first chemoattractant or chemokine receptor to be cloned. Two human homologs were subsequently identified and designated FPRL1 and FPRL2. Of these, only the former responds, though poorly, to formyl peptides. Although the FPR is expressed predominantly in neutrophils, it also appears to be expressed in monocytes, dendritic cells, hepatocytes, endothelial cells, and the nervous system. FPRL1 and FPRL2 are expressed in some of the same cell types as well as unique sites. Although the human FPR gene family consists of only three members, the number varies considerably in other species, with six members in the murine gene family for example. Thus, distinct evolutionary pressures seem to dictate the repertoire of formyl peptide receptors in a given organism.

The role of the FPR in antimicrobial defense has recently been directly demonstrated in knockout mice lacking mFPR1, the homolog of the human FPR. Although such mice appear normal under unstressed conditions, they demonstrate a lack of neutrophil responses to N-formyl-methionyl-leucyl-phenylalanine (fMLP or fMLF) challenge as well as an increased susceptibility to infection with *Listeria monocytogenes*. Furthermore, in humans, two variant alleles of the FPR representing single point mutations that disrupt normal function are associated with localized juvenile periodontitis, a result of periodontal bacterial infection. It is perhaps surprising that such defects do not lead to more serious conditions.

Complement Receptors

C5a Receptor

At the same time that formylated peptides were being characterized as chemoattractants, proinflammatory peptides derived from the complement system were similarly being studied. Two receptors have been identified that respond to the cleavage products of the complement components C3 and C5. The C5a receptor is similar in size to the FPR and closely related to it phylogenetically. Interestingly, there exists little interspecies homology in the extracellular regions of the C5a receptor, despite apparent contact sites with C5a and interspecies activation (C5a from one species activating the receptor from another species). Antibodies directed against peptides representing the amino terminus of the receptor and amino-terminal truncations of the receptor prevent C5a binding. As the antibodies do not block activation of the receptor by synthetic C5a carboxy-terminal peptides, the amino terminus of the receptor may represent a secondary nonactivating binding site and not the primary effector site. Mutagenesis studies suggest a critical role for a number of aspartic acid residues in the

amino terminus. Recent evidence is consistent with C5a receptor dimerization, a phenomenon now demonstrated for many GPCRs with unclear functional consequences. Studies of genetically engineered mice lacking the C5a receptor demonstrated that this receptor plays a critical role in clearing pulmonary pseudomonas infections, with mice succumbing to pneumonia despite a marked neutrophil influx.

C3a Receptor

The C3a receptor is unusual in that it possesses a second extracellular loop of nearly 175 amino acids compared to about 30 amino acids for most GPCRs including the C5a receptor and FPR family. Deletion analysis of this loop suggests that it plays a role in C3a binding and receptor activation, although as much as two-thirds of the loop can be deleted without affecting activity. It is thought that the second extracellular loop may replace the function of the amino terminus of the C5a receptor in providing a secondary nonactivating binding site. Recent studies with C3a receptor knockout mice suggest a role for the receptor in allergic airway diseases such as asthma.

Ligands

Chemotactic Peptide Receptors

The first leukocyte chemotactic factors to be defined structurally were the N-formyl peptides. These consist of short oligopeptides consisting of three to six hydrophobic amino acids, with the amino terminal residue being formylated. Such peptides are not synthesized by eukaryotic cells *per se*. There are only two sources of N-formylated peptides in nature: one endogenous to eukaryotic cells, mitochondria, and the other exogenous, bacteria. Each of these sources initiates protein synthesis with an N-formyl methionine tRNA. This suggests an ideal targeting mechanism for leukocytes to sense bacterial infection or cell damage through the release of peptides containing N-formyl-methionyl peptides. The first chemoattractant peptide was isolated from bacterial lysates and was identified in 1976 as fMLP. This agonist is capable of eliciting the full complement of leukocyte functions from chemotaxis to degranulation to superoxide production at concentrations ranging from pM to nM. The FPR is the primary receptor responsible for cellular stimulation in these concentration ranges, whereas FPRL1 responds to fMLF at μ M concentrations. Both the FPR and FPRL1 have recently been shown to be activated by a diverse collection of endogenous as well as exogenous peptides. These include nonformylated peptides from exogenous sources such as *Helicobacter pylori* and HIV-1 envelope proteins as well as endogenous host-derived proteins such as serum amyloid A and peptides from annexin I, amyloid precursor protein, and prion protein among others. Lipoxin A4, a lipid metabolite, has also been reported to activate FPRL1. The biological relevance of these agonists remains to be determined. Finally, a number of nonformylated high-affinity peptide agonists for the FPR and FPRL1 have been isolated from peptide libraries. A number of antagonists have also been identified, including Boc-FLFLF, cyclosporine H (a fungal metabolite), and deoxycholic acid (a bile acid).

Complement Receptors

C5a

The anaphylatoxin C5a, the most potent plasma-derived chemotactic factor, is a 74-amino-acid peptide/protein released from the α -chain of C5 by either the classical or alternative pathway C5 convertases. Structurally, the protein consists of four antiparallel α -helices held together by disulfide bonds and an 11-amino-acid carboxy terminal tail. Unlike the small formyl peptides, C5a appears to interact with its receptor at two sites. The α -helical bundle interacts with the receptor's amino-terminal domain, whereas the tail appears to insert itself into the transmembrane bundle of the receptor, thereby activating the receptor. Synthetic peptides representing the carboxy-terminal ten amino acids are full agonists, though with potencies 1000–10 000 lower than C5a itself. The sequence Gln–Leu–Gly–Arg is a highly conserved effector sequence in C5a from numerous species. Substitution of residues within this region can greatly augment potency. Removal of the final arginine residue in C5a results in greatly decreased potency, ranging from 1000-fold decrease for spasmogenic activity to 10-fold for chemotactic activity.

C3a

Less is known regarding the interactions between C3a and its receptor. C3a is a 77-amino-acid protein released from the α -chain of C3 by either the classical or alternative pathway C3 convertases. C3a and C5a, despite having common genetic ancestry, have markedly different sequences. Only 13-amino-acid positions have been totally conserved between C3a, C5a, and the related C4a molecules from numerous species analyzed. Six of these residues represent immutable cysteine residues that direct folding of the protein. Again, the carboxy-terminal sequence seems to define molecular action as the terminal sequence Leu–Gly–Leu–Ala–Arg is conserved in all known C3a molecules. C3a appears to interact with both portions of the large second extracellular loop of the receptor as well as charged residues at the transmembrane boundaries of this loop. For both the C5a and C3a receptors, insertion of the carboxy terminus of the anaphylatoxin into a binding pocket formed by the transmembrane helices of the receptor appears essential to receptor activation.

G Proteins

Following ligand binding and the commensurate activation of the receptor, GPCRs interact with G proteins initiating a vast array of intracellular signaling (Figure 1). Of the four major G protein subfamilies ($G_{s/r}$, G_i , $G_{q/11}$, and $G_{12/13}$), chemoattractant/complement receptors activate primarily the G_i family of G proteins. This is demonstrated by the inhibition of virtually all chemoattractant receptor-mediated cell activation by pertussis toxin, a bacterial toxin that inactivates G_i (and closely related G_o) α -subunits of G proteins. G proteins consist of three subunits: the guanine nucleotide-binding α -subunit, and the nondissociable membrane-associated $\beta\gamma$ -subunit dimer. Receptor activation catalyzes the exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the α -subunit followed by activation of the α - and $\beta\gamma$ -subunits. Hydrolysis of the bound GTP by the intrinsic activity of the G_{α}

protein, accelerated by a family of regulators of G protein signaling (RGS) proteins, inactivates the protein, and allows reassembly of the inactive $\alpha\beta\gamma$ -heterotrimer.

Effector Proteins

Chemoattractant-mediated G protein activation leads to a plethora of downstream signaling events. Although G_i proteins are generally considered to inhibit adenylyl cyclase activity, in the case of most chemoattractant and chemokine receptors, G_i activation leads to $G_{\beta\gamma}$ -mediated activation of phospholipase $C\beta_2$, resulting in the production of inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 generation results in the release of calcium from intracellular endoplasmic reticulum stores, often followed by the influx of calcium from the extracellular environment through ion channels. The calcium and DAG in turn activate protein kinase C (PKC). Receptor-mediated phospholipase A_2 activation results in the generation of arachidonic acid and subsequently prostaglandins and leukotrienes. Phosphatidylinositol 3-kinase (PI3K) also plays a critical role in leukocyte activation and chemotaxis in particular. MAP kinase family members ERK, p38, and Jnk have all been shown to be essential to cellular activation events. The low-molecular-weight monomeric G proteins Rac and Rap, as well as their associated regulatory proteins and downstream effectors, are important mediators of actin assembly/chemotaxis and superoxide production.

Receptor Regulation

The dysregulated activation of leukocytes is a serious contributing factor to numerous chronic inflammatory diseases such as arthritis and reperfusion injury in ischemic tissues following myocardial thrombosis and stroke. Activated chemoattractant/complement receptors are rapidly phosphorylated following ligand binding and receptor activation. This can be mediated either by G-protein-coupled receptor kinases (GRKs) that are specific for the active state of GPCRs or by second messenger kinases such as protein kinase A and PKC that phosphorylate active and inactive receptors. The latter provides a mechanism (termed heterologous desensitization) by which GPCRs such as the FPR, which has no PKC phosphorylation sites, can desensitize the C5a receptor, which is phosphorylated by PKC, leading to decreased G protein coupling (see Figure 1). Since any inflammatory process is likely to lead to the generation of multiple simultaneous chemoattractant signals, these regulatory mechanisms create a hierarchy of chemotactic responsiveness to different ligands. GRK phosphorylation of chemoattractant receptors, which occurs within the carboxy terminus of the receptor at sites distinct from PKC sites, leads to binding of arrestins and receptor internalization. Arrestin binding further uncouples receptors from G proteins by physically preventing access of G proteins to the receptor (termed homologous desensitization). For many GPCRs, arrestin binding also mediates interactions with clathrin and adapter proteins such as AP-2, initiating receptor translocation to clathrin-coated pits and subsequent internalization. Contrary to this paradigm, the FPR internalizes in an arrestin-independent manner. However, arrestin is required for recycling of the FPR back to the cell surface. Arrestins have also been shown to play

Figure 1 Signaling and regulation of chemoattractant/complement receptors in leukocytes. Binding of a chemoattractant (agonist) results in a conformational change in the FPR, which activates G proteins. Dissociation of GDP from the α -subunit is followed by GTP binding and dissociation of the α -subunit from the $\beta\gamma$ -subunits, both of which can stimulate downstream effectors. The $\beta\gamma$ -subunits provide a docking site for G-protein-coupled receptor kinases (GRKs), which phosphorylate (P) the ligand-bound, activated receptor. $\beta\gamma$ -Subunits also activate phospholipases, which generate diacyl glycerol (DAG) and inositol trisphosphate (IP_3) and phosphatidylinositol-3 kinase (PI 3 kinase), which generates phosphatidylinositol trisphosphate (PIP_3). PIP_3 is an activator of numerous pathways, including those culminating in low-molecular-weight (LMW) monomeric G proteins of the Ras superfamily that regulate actin assembly and ultimately chemotaxis. IP_3 production results in the release of Ca^{2+} from intracellular stores and, together with DAG, activates protein kinase C (PKC). PKC is capable of phosphorylating many proteins, including complement receptors, such as the C5a receptor, resulting in their heterologous desensitization. Desensitization of the FPR occurs through the binding of arrestin to GRK-phosphorylated receptors. In addition to preventing further signaling through heterotrimeric G proteins, arrestins serve as scaffolds for multiple MAP kinases, resulting in their localized activation. Together, these and many additional pathways produce cellular responses, including superoxide generation, degranulation, chemotactic cell movement, and transcriptional activation resulting in cytokine production.

an important role in the scaffolding of numerous intracellular signaling cascades, including Src and MAP kinases. This mechanism is believed to provide both spatial and temporal regulation of the downstream effectors.

Drug Discovery and Receptor Technology

GPCRs represent 50% of the targets of drugs on the market today. In particular, the family of chemokine/chemoattractant receptors is highly sought after target as the receptors are involved in immune disorders such as chronic inflammation and asthma, cancer, and many more disease states. The formyl peptide receptor, in particular, has served as an important model for the real-time analysis of ligand-receptor interactions based on the detection of fluorescent peptide ligands by solution fluorescence, flow cytometry, and microscopy. These

ligands and receptors have provided the basis for developing subsecond kinetic resolution of molecular assemblies and disassemblies by flow cytometry as well as small volume, high-throughput flow cytometric platforms for screening. Recently, small molecule (nonpeptide) agonists and antagonists have been identified that exhibit selectivity for the FPR and FPRL1.

Glossary

Absorption The process of interaction of a molecule with a photon to produce an excited state.

Excited states More precisely, electronically excited states; they are usually generated by light absorption in molecules containing a large number of conjugated double bonds. Singlet and triplet states are distinguished by their spin states, leading to large differences in their lifetimes. If the ground state is a singlet, as in practically all dyes, excited singlet states are short lived (10^{-12} – 10^{-8} s), and the lowest triplet states are long lived (up to milliseconds). If the ground state is a triplet, one of the rare cases being molecular oxygen, the lowest excited singlet state is long lived.

Fluorescence It is the spontaneous decay of an excited state to the ground state with the concomitant emission of the energy in the form of a photon. Together with phosphorescence, which is distinguished from fluorescence mainly by its longer timescale ($>10^{-6}$ vs. $<10^{-8}$ s), they are often summarized as luminescence.

Internal conversion (IC) The spontaneous decay of an excited state to the ground state with the concomitant release of the energy in small packages as heat. It is a so-called loss channel, because the heat is (generally) of no use in biology, but is, by the same token, important in light protection (e.g., by preventing photosensitized generation of reactive oxygen species).

Intersystem crossing (ISC) Conversion of a triplet to a singlet state, or vice versa. ISC is generally slow (μ s), but can be sped up by heavy metals or in radical pairs.

The latter process is responsible for the generation of triplets in reaction centers.

Isoprenoids These compounds are formally derived from the branched C_5 -unit, isoprene. Besides carotenoids, important natural isoprenoids are the steroids, gibberellins (plant hormones), mono-, sesqui-, and diterpenes (fragrances and flavors), and polymers such as rubber.

Photodynamic therapy (PDT) This is the diagnostic and therapeutic application, for example, in treatment of cancer, which relies on photosensitizing dyes, light, and oxygen to selectively attack cells, virus, tissue, or organs.

Photosensitization The process of indirectly generating reactive oxygen species by triplet energy transfer. A sensitizing dye is excited by light to the singlet state. This converts spontaneously by ISC to a long-lived triplet state, capable of generating reactive oxygen species by several mechanisms.

Photosynthesis The natural process of plants, algae, and certain bacteria by which (sun)light is converted to biochemical energy (carbohydrates), which is eventually the primary source for life on Earth.

Reactive oxygen species (ROS) These highly aggressive and cytotoxic chemicals, including singlet oxygen, superoxide, peroxide, and hydroxyl radicals, are derived from oxygen. They are often produced, directly or indirectly, by action of light.

Tetrapyrroles These are compounds comprised of four pyrrole rings. In natural tetrapyrroles, they are linked either directly or by single carbon bridges, and they can be linked in a linear (bile pigments) or a cyclic fashion (hemes, chlorophylls, vitamin B_{12} , and F430).

The green (Greek 'chloros') of leaves (Greek 'phyllos') is a mixture of two water-insoluble pigment classes: chlorophylls, mainly the blue chlorophyll (Chl) *a*, and carotenoids, mainly β -carotene. Both pigment classes cooperate in photosynthesis to safely capture light provided by the Sun, as the primary energy source for life on Earth. Chlorophylls are responsible for light harvesting and its transduction to an electrochemical potential across the photosynthetic membrane which ultimately serves to reduce atmospheric carbon dioxide to carbohydrates. Thus, the energy of the fleeting photons is stored in increasingly longer-lived products: first, Chl excited states are generated with lifetimes in the order of several nanoseconds (10^{-9} s), then a membrane potential which is stable for seconds, then high-energy products such as adenosine triphosphate and reduced nicotinamide adenine dinucleotide phosphate that live for minutes or even hours, and eventually storage products such as starch and sugars.

The carotenoids can act, too, as light-harvesting pigments, in the blue spectral regions (450–530 nm) where Chls have

only little absorption. Their major and indispensable function is, however, to safely drain excess excitation energy from the chlorophylls and convert it into heat. By biological standards, photons are a high-energy source which is potentially highly toxic (sunburn). Mutants lacking carotenoids, or enriched in chlorophylls, are quickly bleached and killed in sunlight. The combination of chlorophylls with carotenoids allows photosynthetic organisms a careful balance between successfully competing with other organisms for capturing light, and being killed by an overdose of it. Photosynthesis based on these two pigments has, therefore, conquered nearly all habitats on earth where light is available. It has produced the atmospheric oxygen we breathe, and fixes $\sim 10^{11}$ tons of carbon annually. The greening and degreening of the vegetation is probably the most obvious life process on Earth, visible clearly from outer space. The widespread occurrence of photosynthesis in nearly all ecotopes is paralleled by considerable variations of the photosynthetic apparatus, including the pigments. It is this variety of chlorophylls and carotenoids,

and also basic similarities among the different species, which are dealt within this article.

Chlorophylls

Structures

The basic structure of chlorophylls is the porphyrin macrocycle. It is comprised of four pyrrole rings containing each four carbons and one nitrogen, which are joined via one-carbon bridges to an aromatic macrocycle (Figure 1). The four nitrogens face inward, creating a hole which is ideal for binding metal ions. In the chlorophylls, this central metal is almost always magnesium (Mg). Although many of the peripheral substituents vary among the different structures, all chlorophylls contain an additional five-membered ring E and, with the exception of some Chl *c*, the C-17 propionic acid side chain is esterified by a long-chain alcohol, most commonly the C₂₀

terpenoid alcohol, phytol. The chlorophylls can further be classified by the degree of unsaturation of the macrocycle, into the fully unsaturated true porphyrins, the chlorins with an unsaturated ring D and the bacteriochlorins in which ring B is unsaturated, too.

Spectroscopy

The spectral properties of chlorophylls are described by a modified version of the general four-orbital model of porphyrins resulting in four major absorptions termed Q_Y, Q_X, B_Y, and B_X, in the near-ultraviolet (NUV), visible (Vis), and near-infrared (NIR) spectral regions. The type of spectrum is mainly determined by the degree of unsaturation of the tetrapyrrole macrocycle (Figure 2): in the fully unsaturated Chl *c* containing a porphyrin macrocyclic system, the B-bands around 400 nm overlap, the Q_Y-band around 620 nm is weak, and Q_X-band is visible only with special techniques. In chlorin-type

(a) Sometimes esterified, (b) Acrylic side chain at C-17 (17¹-17² double bond).

(c) 2,6-Phytadienol in green bacterial reaction centers, (d) no central metal.

Figure 1 Structures of common chlorophylls. In particular, reaction centers contain a series of specialized chlorophylls that are being dealt with in a survey by M Kobayashi and coworkers in 2006. The structure of chlorophyll *f* has been described by Chen et al. in 2010.

Figure 2 Type spectra of the three chlorophyll classes: porphyrins (Por), chlorins (Chl), and bacteriochlorins (BChl). Note that the bacteriochlorophylls *c*, *d*, and *e* are not bacteriochlorins, but rather chlorins (see [Figure 1](#)).

chlorophylls (Chl *a*, *b*, *d*, BChl *c*, *d*, *e*), the B-bands are reduced in intensity, the Q_x-band increased to near equal intensity and redshifted to ~660 nm. In the bacteriochlorin-type chlorophylls (BChl *a*, *b*, *g*), the B-bands are blueshifted to <400 nm and well separated, the Q_x-band is even more increased in intensity and redshifted to ~780 nm, and in these pigments the Q_y-band also has gained in intensity and becomes visible around 570 nm. By these characteristics, the chlorophyll type can be readily determined from the spectra, and often also other details like substitution pattern, ligation to the central metal (e.g., by the protein), or aggregation.

Chlorophylls dissolved in organic solvents have long-lived-excited states (~10⁻⁸ s). They are, therefore, highly fluorescent. Consequently, there is significant intersystem crossing possible to the triplet state. This gives rise to phosphorescence and, more significantly, under aerobic conditions to the generation of highly reactive oxygen species (ROS) like singlet oxygen. Chlorophyll solutions, therefore, bleach rapidly by attack of the pigment by these ROS, and chlorophylls injected into animals lead to severe 'sunburn' and destruction of tissue. This effect is used in photodynamic therapy of cancer.

In chlorophyll aggregates, there is generally a pronounced redshift of the Q_y-band, and the excited-state lifetimes (and thereby fluorescence and phosphorescence) are drastically reduced due to rapid conversion of the excitation energy into heat by internal conversion (IC). These effects are summarized under the term 'concentration quenching' and probably due to the presence of 'traps' in the large aggregates in which the excitation is highly delocalized over many pigment molecules. An exception are the chlorosomes of green bacteria: they contain aggregates of bacteriochlorophylls *c*, *d*, or *e* which show little concentration quenching, or only under conditions of excess light.

Aggregation is also observed in photosynthetic pigment-protein complexes, where it is considered a major organizing

force. In addition, there is a general redshift of all bands brought about by the protein environment. There is, however, a very distinct difference to aggregates formed *in vitro*: although excitation energy is mainly transformed to heat in the latter, this loss is avoided in the pigment protein complexes. Isolated light-harvesting complexes (LHCs), which contain the vast majority (≥99%) of chlorophylls, therefore, show, under moderate light intensities, high fluorescence. The avoidance of concentration quenching in these aggregates is in fact one of the major, mechanistically still unresolved tricks of efficient photosynthesis. In the reaction centers (RCs), the lifetime is short, but here the excitation energy is used to create, with quantum efficiencies near 100%, a charge separation across the photosynthetic membrane which is otherwise an insulator, thus creating a long-lived membrane potential. This energy transduction process is at the heart of photosynthesis, and the high-resolution crystal structures of RC together with extensive spectroscopy at high time resolution have provided a general picture on how this process is working. In the photosynthetic apparatus, LHCs containing >99% of the chlorophylls are coupled to RC, such that now the excitation energy of the former is efficiently transferred to the latter. By this means, the absorption of the RC is increased by orders of magnitude, and different numbers and types of LHC can be combined to adapt to the prevailing light conditions. As the amount of protein is much less in LHC than in RC, the biosynthetic expenses for such a coupled system are at the same time strongly reduced. There is nonetheless an often overlooked loss of energy that is inherent to the antenna/RC concept: antennas absorb over most of the Vis and NIR spectral region, and the energy is transported to the RCs absorbing, and working with low-energy red or NIR excitation. By this process, any excess energy of the absorbed photons (compared to the RC energy) is lost as heat. Depending on the system used, these losses can be substantial, but must be ecologically still less than with other solutions.

Occurrence and Functions

The majority of chlorophylls, both in terms of structure diversity and quantity, serve as light-harvesting pigments. Taken together, they absorb light across most of the spectral range from 350 to 1020 nm, with a gap only in the region from 500 to 600 nm where carotenoids and biliproteins add to light harvesting. No organism contains all types of chlorophylls; however, so different organisms occupy different spectral niches, and the pigmentation is an important taxonomic criterion. Due to the more demanding energetics, oxygenic organisms (plants, algae, and cyanobacteria) can only use light <750 nm, while the anoxygenic photosynthetic bacteria have specialized in the NIR with extremes such as the purple bacterium, *Blastochloris viridis*; reaching 1020 nm. RCs contain chlorophylls, too, including besides the bulk pigments some specialized derivatives. They form a chain of pigments across the membrane, over which in a stepwise fashion electrons are transferred from the primary donor, a pair of chlorophylls located on the periplasmic side of the membrane, to the acceptors on the cytoplasmic side. It should be mentioned that some chlorophyll-like pigments perform other functions in nature: examples are certain deep-sea fish using chlorophylls as visual pigments, and the marine worm, *Bonella viridis*, where chlorophyll derivative acts as a sex determinant.

Chemical Properties

Chlorophylls are large, aromatic molecules with a central hole fit to complex many metals. They are basically planar and fairly rigid, but small deviations from planarity are observed in most structures of chlorophyll proteins. Although the macrocyclic system is quite stable, the functional groups and the central Mg render the chlorophylls quite labile. Under acidic conditions, the central Mg is lost rapidly, and the long-chain alcohol residue hydrolyzed. The central Mg is also readily replaced by other, more stable metals such as Zn, Ni, Ag, Cu. As most of these replacements lead to pigments that are less efficient for photosynthesis, part of the metals' toxicities relate to impairment of photosynthesis. There is one exception, however: a photosynthetic bacterium from a strongly acidic biotope contains a bacteriochlorophyll *a* in which the central Mg is replaced by Zn, thereby probably stabilizing it to acid-induced demetalation. Under alkaline conditions, the isocyclic ring is modified extensively. The macrocycle can be opened at the methine bridges, both (photo) chemically and enzymatically during degradation.

After binding to the tetrapyrrole, the central Mg still has free valences, which are important for aggregation and, in particular, for interactions with the natural protein environment. By interactions with suitable amino acids (e.g., histidin, methionin, and glutamate) they can be positioned properly for efficient energy or electron transfer. In the LHC of green bacteria, the chlorosomes, the coordinating properties of the central Mg and the ligation of special peripheral substituents combine to form large aggregates of bacteriochlorophylls *c*, *d*, and *e* that are nearly devoid of protein.

Metabolism

The formation of chlorophylls can be separated in stages. The first is the synthesis of 5-aminolevulinic acid (ALA), the basic

building block of all tetrapyrroles. In most photosynthetic organisms, it is formed from glutamic acid, involving an intermediate (Glu-tRNA^{Glu}) which is otherwise only involved in protein synthesis. Some photosynthetic bacteria (purple bacteria) use, like humans, the alternative C₄+1-pathway in which succinyl coenzyme A is condensed with glycine. The second stage is ubiquitous in all organisms and for all natural tetrapyrroles. The two ALA first react to yield a pyrrole (porphobilinogen), a five-membered ring containing one nitrogen atom. Four such pyrroles condense to a linear tetrapyrrole, and then cyclize in a remarkable reaction in which one of the pyrroles is flipped. At this stage, the pathways to vitamin B₁₂, certain hemes, and certain Ni-tetrapyrroles branch off. In chlorophyll biosynthesis, the resulting cyclic tetrapyrrole is transformed by a series of decarboxylation and oxidation reactions to protoporphyrin. It is noteworthy that the latter is the first colored product in the synthesis, and highly phototoxic like most porphyrins. The organisms, therefore, avoid, over large stretches of biosynthesis, the formation of such potentially harmful precursors. They also regulate very tightly the amount of ALA in order to avoid any overproduction of protoporphyrin. Any deregulation of this process, as any other alteration of the biosynthesis can result in severe damage and often death. The next stage of the pathway is the insertion of Mg, which is thermodynamically unfavorable and energy requiring, and the formation of the isocyclic ring from the propionic acid side chain at C-13. Although the synthesis of Chl *c* is practically complete at this stage, all other chlorophylls require further modifications, viz., the reduction of ring D (chlorins) and B (bacteriochlorins), modifications at the periphery, and the condensation of the C-17 propionic acid with the long-chain alcohol derived from the isoprenoid pathway.

Chlorophyll degradation has been studied in some detail for Chl *a* and *b*, it involves the (light independent) ring opening to the much less-phototoxic open-chain tetrapyrroles (bilins). Very little is known on the degradation of the other pigments, and on potential functions of the degradation products.

Applications

Unmodified chlorophylls are too labile for most practical use, but some derivatives are used as dyes for cosmetics and food (Cu-chlorophyllin), and in photodynamic tumor therapy (chlorins and bacteriochlorins). The chlorophyll used, for example, in certain health care products is a complex mixture of degradation products. The best source for Chl *a* is the cyanobacterium *Spirulina platensis*, which is available commercially. Chl *a/b* mixtures can be obtained from all green plants. Bacteriochlorophyll *a* can be obtained from certain photosynthetic bacteria that can be grown in the dark. All other chlorophylls are less readily accessible, thereby limiting their applications.

Carotenoids

Structures

Carotenoids are much more widespread and not confined to photosynthetic organisms, and structurally and functionally more diverse than chlorophylls. There are currently more than

800 natural carotenoids known, each can, furthermore, form several *cis-trans* isomers and be additionally modified. Chemically, most carotenoids are tetraterpenes: two C_{20} -units (originally geranyl-geraniol) are joined tail-to-tail to a chain of 32 carbon atoms bearing eight methyl side chains. Often, this basic carbon C_{40} -skeleton is either retained, or only slightly modified, for example, by cyclization at one or both ends (Figure 3). However, much more extensive modifications are possible, including isomerization and rearrangement of the double bonds, removal of carbon atoms, the introduction of oxygen-containing functional groups, and their glycosylation or acylation. These modification seems to be particularly

far-reaching in carotenoids dedicated to light harvesting, as exemplified by peridinin; a highly modified C_{37} pigment from algae. Some carotenoids are also derived from C_{30} or C_{50} skeletons.

Spectroscopy

The rod-shaped carotenoids show the typical absorption spectra of linear polyenes, which are characterized by some unusual features. (1) The lowest energy $S_0 > S_1$ transition located in the red to NIR spectral range, is extremely weak (optically forbidden) in most carotenoids, and has been accurately determined

Figure 3 Examples of carotenoid structures.

only in few pigments by special techniques. (2) The most intense absorption, responsible for the yellow–orange color of most carotenoids, is a series of closely spaced, sometimes overlapping bands in the 400–550 nm range. With an increasing number of conjugated double bonds, this absorption is shifted, in an asymptotic fashion, to the red. The sub-bands are generally well resolved, but can be broadened to a degree that they appear only as a single, somewhat structured band. (3) There several other transitions between these two bands, which are also optically forbidden and, therefore, very weak. (4) *cis*-Carotenoids show an additional, typical band 100–150 nm to the blue of the main absorption (see Figure 4 for type spectra). Although the ‘forbidden’ bands do not contribute to absorption, they are fundamentally important for the biological functions of carotenoids. The states responsible for them can be reached indirectly, for example, after absorption into the energy-rich major absorption band and IC, or by energy transfer from neighboring pigments like chlorophylls by electron exchange and they thereby contribute to energy transfer and dissipation.

Most carotenoids show extremely rapid IC from all excited states and, therefore, negligible fluorescence. Their excited state have generally lifetimes of only a few picoseconds, and reach even in extreme cases like peridinin only 100 ps. Carotenoids have unusually low-lying triplet states, many of them even below the energy of singlet oxygen (1250 nm). Again, they can be reached only indirectly, mainly via short range (≤ 3.5 Å) energy transfer from triplets (e.g., of chlorophylls) or from singlet oxygen. As the latter are highly cytotoxic, this property is functionally very important, too, because it is the basis for the protective effects of carotenoids.

The spectral properties of carotenoids can be modified considerably by interactions with the protein. A spectacular case is the color change of astaxanthin from orange to green when it is bound in the crustacean protein, α -crustaxanthin, and its reversion when the protein is denatured by boiling.

Occurrence and Functions

Carotenoids are almost ubiquitous in living organisms, even though animals including man cannot synthesize them but have to rely on dietary supplies.

Their functions are as diverse as their structures. In photosynthesis, their essential function is the protection of the photosynthetic apparatus under conditions of light overload. Whenever the RC cannot follow the energy input from the LHC, the long-lived-excited states of the chlorophylls pose a deadly danger to these organisms due their potential of generating ROS. This is prevented by carotenoids at several levels. They can accept excess energy via their low-lying forbidden states, they can quench chlorophyll triplets by triplet energy transfer to the low-lying carotenoid triplets, and they can quench ROS by energy transfer, for example, from singlet oxygen, or addition of ROS to the double-bond system. All these processes require very close distances between donor and acceptor, which are nicely corroborated by X-ray structures of photosynthetic complexes. All chlorophyll-containing LHC have carotenoids in contact with certain chlorophylls, and specialized 15-*cis*-carotenoids are found in the RC. In the LHC, protective carotenoids seem to be positioned strategically at critical sites where the energy is funneled to the RC. As energy will flow preferentially downhill, the accepting states of protective carotenoids need to lie very close to those of the donors.

As ROS are also important in the attack of infectious agents by the immune system, bacteria synthesize carotenoids for their protection, and many of the more virulent forms are deeply colored by carotenoids.

Carotenoids also protect from light, simply by their function as light filters, removing NUV and blue light by virtue of their high absorption in these spectral regions, and their capacity to rapidly degrade the excitation energy to heat by IC. Certain algae tolerant to extreme light stress contain droplets of pure carotenoids, and many nonphotosynthetic organisms

Figure 4 Type spectra of carotenoids.

synthesize more carotenoids when subjected to increasing light intensities. As nonphototoxic pigments, carotenoids often function as 'safe' dyes in nature. Examples are the colors of flowers used for attracting insects, or of crustaceans to blend into the marine background.

In spite of their general protective function, carotenoids have also been adapted by photosynthetic organisms for light harvesting in the 'green gap' (470–600 nm) where chlorophylls absorb only poorly, in particular in microalgae and phototrophic bacteria which, unlike higher plants, cannot outgrow their competitors. Two factors are important to this function. One is the development of carotenoids in which the excited-state lifetime is somewhat increased and, therefore, IC reduced. The two most-abundant carotenoids, fucoxanthin and peridinin, show this very nicely with lifetimes reaching up to 100 ps. The second factor is positioning of carotenoids in contact with chlorophylls, thereby speeding up energy transfer sufficiently to be effective within the short excited-state lifetimes (electron-exchange mechanism). As the direction of energy transfer depends on the relative energies of the excited states, they have to be properly ordered: for light-protection the carotenoid excited state needs to be below that of a neighboring chlorophyll; for light harvesting it needs to be above. There is evidence that plants and some algae use, in the so-called violaxanthin cycle, subtle structural modifications in order to manipulate the excited state energies of carotenoids, thereby converting a light harvesting into a protecting pigment, and vice versa, in response to the light supply and energetic demands.

Last but not least are carotenoids precursors for certain important metabolites. Only two examples are stated. (1) Retinal, the chromophore of the visual pigment rhodopsin, is derived from carotene. As the latter cannot be synthesized by animals, they need it supplied as provitamin A. Retinal derivatives are also required for other regulatory functions. (2) Certain fragrances of roses have also been shown not to be synthesized directly, but rather to be breakdown products of the flowers' carotenoids.

Chemical Properties

Due to their hydrocarbon skeleton, almost all carotenoids are insoluble in water and well soluble in nonpolar solvents. The conjugated double-bond system is chemically moderately stable. It is subject to rearrangements, in particular in the light, and to additions, for example, of oxygen. The chemical properties of the more highly modified carotenoids are determined by their particular functional groups. Only few examples shall be given: the epoxide function present in violaxanthin is very acid sensitive, *cis*-carotenoids are readily (photo)converted to the more stable *trans*-carotenoids, and lactones or esters can be hydrolyzed by acid or base.

Metabolism

Carotenoids, like all terpenoids, are products of the isopentenyl-pyrophosphate metabolism. The basic C₅ building block can be synthesized either by the mevalonate pathway from acetyl-coenzyme A, or via the more recently discovered deoxyxylulose pathway. The latter seems to be the pathway leading to carotenoids in most photosynthetic organisms.

One of the resulting C₅-units (dimethylallyl-pyrophosphate) is condensed sequentially by prenyl transferases in a head-to-tail fashion with three isomeric C₅-units (isopentenyl-pyrophosphate) to yield geranylgeranyl-pyrophosphate (GGPP), an important branching point in terpenoid metabolism. GGPP is, for example, directly or indirectly, the substrate for esterifying the C-17 propionic acid side chain of most chlorophylls, thereby linking the tetrapyrrole- and terpenoid pathways. The biosynthesis directed to most carotenoids begins with a tail-to-tail condensation of two molecules of GGPP by the dedicated enzyme, phytoene synthase. Having only three conjugated double bonds, the resulting phytoene is still uncolored. Dehydrogenation by desaturases via phytofluene to lycopene is common to most carotenoids currently known. C₃₀ carotenoids are derived from condensation of two C₁₅-units (farnesol-pyrophosphate) in an otherwise very similar reaction sequence. A wide variety of enzymes, many of them still only partly characterized, is responsible for further structural modifications. They include cyclases to form the end rings characteristic of many carotenoids, oxygenases to introduce OH groups, isomerases and (de)hydrogenases to modify the double-bond system, and many more follow-up enzymes allowing for the structural variety of carotenoids. Although *cis-trans* isomerases related to the visual systems are well studied, the formation of 15-*cis*-carotenoids in the RC is unclear and may be a spontaneous reaction during incorporation of the respective 15-*trans* isomer.

Applications

The most frequent applications of carotenoids, which are of considerable economic importance, are as food colorants, as dietary supplies, and as sun screens in cosmetics. Food is also frequently colored indirectly, for example, by supplying carotenoids or carotenoid-rich algae in the feedings of fish (salmon) or poultry (chicken eggs). Provitamin A (β-carotene) is supplied not only directly but also indirectly, for example, as milk supplement. Industry-scale synthetic methods have been developed, natural sources are algae such as *Hematococcus*, plants such as carrots, and genetically manipulated bacteria.

Glossary

Binary fission Mechanism, similar to that occurring in bacteria, by which the chloroplast divides independently from the cell division.

Envelope Pair of concentric membranes enclosing the chloroplast.

Etioplast Organelle which is the counterpart of chloroplast and develops in dark-grown seedlings of flowering plants.

Prolamellar body Tridimensional semi-crystalline aggregate of the etioplast tubular membranes.

Thylakoids Flattened cisternae or saccules intercommunicating, which form the closed inner membrane system of chloroplast.

Chloroplast Origin

Some 3.5 billion years ago, an ancestral form of cyanobacterium with the contemporary presence in the cell of a green and a purple bacterium anoxygenic photosystem appeared on the earth. A deep re-elaboration of the new photosynthetic apparatus, which required about 1 billion years, led, at the end, this kind of microorganism to gain the ability to use water as source for electrons, thus giving rise to the oxygen-evolving photosynthesis. This occurred through: the link in series of the two photosystems; the change of bacteriochlorophyll with chlorophyll absorbing at shorter and more energetic wavelength; the rise of the P680 (the photoactive chlorophyll of photosystem II, derived from the purple bacterium one) midpoint reduction potential over that of $\text{H}_2\text{O}/\text{O}_2$ (+0.82 V); the evolution of a Mn-protein complex able to split water-releasing oxygen, electrons, and protons.

The start of the oxygenic photosynthesis was a central event in the life development on our planet, even deemed the Big Bang of life. The oxygen release in the environment changed the face of the Earth by transforming the anaerobic atmosphere to one suitable for the evolution of aerobic forms of life.

A free-living aerobic prokaryote (probably a *rickettsia*-like α -proteobacterium), endosymbiotically enslaved by an anaerobic protoeukaryote, gave rise to the mitochondrion and this allowed eukaryotic heterotroph organisms to evolve.

Successively, a cyanobacterium-like prokaryote with oxygenic photosynthesis, engulfed by an aerobic heterotroph protoeukaryote, originated the chloroplast.

This latter endosymbiotic event, which took place about 1 billion years ago, was of enormous importance, because it triggered the evolution of photosynthetic eukaryotes and even led, as a consequence, to the expansion of the heterotroph forms of life on the Earth. The photoautotroph organisms, in fact, are the primary producers which supply with energy and organic matters to most of ecosystems.

During the evolutionary route which changed it into the chloroplast, the cyanobacterium-like ancestor underwent substantial modifications. A significant event was the transfer of most prokaryotic DNA to the host cell nucleus. The genome of a present chloroplast, actually, codes for ~100 proteins, while

the DNA of a free-living cyanobacterium, like *Synechocystis*, whose entire sequence is known, encodes more than 3000 proteins. The massive 'endosymbiotic gene transfer' possibly occurred to avoid the mutagenic load for organelle genes due to free radicals produced by photosynthetic light reactions, and to escape the accumulation of deleterious mutations caused by the genetic isolation of the organelle DNA in the host cells (the so-called Muller's ratchet).

This transfer of genetic information made it necessary for the chloroplast to recover the proteins encoded in the nucleus and this was achieved by inserting in the nuclear genes a presequence coding for a transit peptide which targeted the chloroplast proteins and redirected them to the organelle.

Another essential change undergone by the evolving chloroplast concerned the photosynthetic light-harvesting pigments. With the exception of some algal groups (Rhodophytes and Cryptophytes), the original phycobiliproteins were replaced by chlorophyll forms, in particular by chlorophyll *b* in green organisms.

Chloroplast Organization

Algae and lower plants have chloroplasts which can vary considerably in shape and size, whereas in higher plants these organelles are commonly lens-shaped and measure ~5–10 μm .

Envelope

The chloroplast (Figure 1) is enclosed by a pair of concentric membranes forming the envelope. The inner envelope membrane is highly selective and contains numerous carriers which regulate the flows of metabolites and ions between chloroplast and the cytosol. The most abundant is the phosphate translocator, which plays a major role in supplying the cell with the products of photosynthesis. The inner membrane also supports some enzymes of biosynthetic pathways, like those of carotenoids, tetrapyrroles, and fatty acids. The outer envelope membrane contains a nonspecific porine-like protein,

which allows ions and metabolites of up to ~10 kDa to pass. It is essentially involved in recognizing the cytosol-synthesized chloroplastic proteins which must be transferred into the organelle. This translocation occurs through two multiproteic complexes, one of them inserted in the outer membrane (translocation outer complex) and the other in the inner membrane (translocation inner complex) of the envelope.

Stroma

The chloroplast internal milieu, called stroma, looks finely granular due to the presence of 70S ribosomes. It contains prokaryotic DNA (Figure 1), RNA, and the entire protein synthesis machinery allowing the organelle to translate its own genetic information. In the stroma are also inserted the soluble enzymes engaged in the numerous biosynthetic pathways. The ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), which catalyzes CO₂ fixation in the first reaction of the Calvin-Benson cycle, is the most abundant enzyme, and is

Note the envelope (e) the inner membrane system formed by stacked granal thylakoids (gt) and single stromal thylakoids (st). Some plastoglobules (pg) are present in the stroma, which look finely granular due to the presence of 70S ribosomes. Scale = 1 μ m. The inset shows the region of a chloroplast stroma with DNA microfibrils (arrow).

even the most abundant protein in the world. It is, actually, a large protein complex consisting of eight small subunits (SSUs) and eight large subunits (LSUs) encoded by nuclear genes and plastidic genes, respectively.

Small roundish inclusions, named plastoglobules, made up of plastoquinones, carotenoids, and proteins, are common in the stroma, where also starch grains of photosynthetic origin can occasionally accumulate.

Thylakoid System

Within the chloroplast a membrane system, the thylakoid system, is present, which contains the multiproteic complexes involved in the light reactions of photosynthesis. The inner membrane system of the chloroplast (Figure 1) consists of coupled lamellae (thylakoid membranes) separated by a narrow intermembrane space. They form flattened cisternae or saccules (thylakoids), intercommunicating to constitute a continuous and closed membrane system, whose internal space (lumen) is totally isolated from the stromal environment.

A feature common to the green plant chloroplasts (Figure 2) is the stacking of thylakoids (granal thylakoids) one upon the other to make piles of saccules named grana (singular: granum), which are interconnected by single unstacked thylakoids running in the stroma (stromal thylakoids). This kind of organization, which gives rise to a huge surface area of thylakoid membranes, acquires functional significance, taking into account that, as stated above, these membranes support the complexes carrying out the photosynthetic light reactions and the correlated electron transport and adenosine triphosphate (ATP) synthesis (precisely: photosystem I (PSI), photosystem II (PSII), the cytochrome *b₆f* complex (Cyt *b₆f*), and the CF₀-CF₁ ATP synthase). These components are diversely and specifically located in the thylakoid membranes (Figure 3). Most of PSII resides in the approached regions of stacked thylakoids (partitions), while PSI and the ATP synthase only occur in the stromal thylakoids and in all the unstacked regions of granal thylakoids (end granal membranes and margins). Finally, the Cyt *b₆f* is rather homogeneously distributed in the thylakoid system.

Figure 2 (a) Three-dimensional scheme of a chloroplast. (b) Particulars of the thylakoid system organization.

Figure 3 Distribution of the multiprotein complexes in the thylakoid membranes.

The thylakoid membranes contain several other proteins, among which of particular interest are a plastid-encoded reduced nicotinamide adenine dinucleotide phosphate (NADPH): plastoquinone oxidoreductase homologous to the complex I of the bacterial respiratory chain and a nucleus-encoded terminal plastoquinol oxidase homologous to the plant mitochondrial cyanide-resistant alternative oxidase. Both these protein components are involved in a physiological process named chlororespiration.

A peculiarity of chloroplast membranes, which distinguishes them from the other cell membranes, is the great abundance of glycolipids, represented by two neutral galactolipids, the monogalactosyldiacylglycerol (MGDG) and the digalactosyldiacylglycerol, which account for 70% of the entire acyl-lipid moiety, and by the anionic sulfolipid sulfoquinovosyldiacylglycerol. Phosphatidylglycerol is the only phospholipid present in the membranes. A feature of all thylakoid lipids is the high concentration of polyunsaturated fatty acids, which maintain membrane fluidity in spite of the high protein/lipid ratio. Nonpolar lipids, such as plastoquinones, phylloquinones, and tocopherols, are inserted in the hydrophobic region of the membrane matrix. Plastoquinone-9, a component of the photosynthetic electron transport chain, is particularly abundant.

Chloroplast Biogenesis

In higher plants, chloroplasts develop from proplastids, which are small undifferentiated organelles present in the meristematic cells. Chloroplast differentiation involves the synthesis of pigments, proteins, and lipids and the structural and functional organization of the whole thylakoid system, as well as the acquisition of the enzymatic components carrying out the numerous metabolic pathways of the mature organelle. These events are accompanied by the increase in the developing chloroplast size and the rise of the organelle number in the cells. Proplastids and young chloroplasts, indeed, can divide through a process of 'binary fission' similar to that occurring in bacteria.

The chloroplast division is independent of cell division, being part of the developmental program that defines the final number of photosynthetic organelles in the mature green cell.

The dependence on both nuclear and own genetic information makes chloroplast biogenesis a quite complex process requiring the coordinated expression of genes located in the two cellular compartments. This takes place through environmental cues, the most important of which is light, and through endogenous nucleus–chloroplast signaling. The nucleus exerts a preeminent role in controlling the chloroplast gene expression. However, also chloroplast-to-nucleus signaling pathways exist that greatly affect the transcription of nuclear genes encoding photosynthesis-related proteins. This kind of 'retrograde' informational flow is triggered by different chloroplast-generated signals, involving, for instance, chlorophyll precursors (porphyrins) or the plastoquinone redox state, and serves not only to correlate the nuclear gene expression with the chloroplast-developmental stage and the organelle functionality but also to achieve a swift photosystem adjustment in response to qualitative and quantitative light changes in the plant growth environment. It is interesting to point out that during the massive transfer of genetic information to the host cell nucleus, the cyanobacterium-like ancestor, which was changing into chloroplast, kept the genes coding for the reaction center proteins in own DNA. The import of this strategy was to make the chloroplast able to adapt more quickly the synthesis of these photosystem key components to the environmental conditions.

Light and Chloroplast Differentiation

In lower vascular plants, as well as in most gymnosperms, the events leading to chloroplast differentiation can occur both in light and in darkness. On the contrary, in the angiosperms, light is a key factor for chloroplast biogenesis and the buildup of the thylakoid system. In these more evolved plants, light, by mediation of phytochromes and cryptochromes (sensing red and blue light, respectively), induces the expression of different nuclear genes (photo-genes) coding for essential chloroplast components. Light, for instance, is required for the transcription of the *RbcS* genes coding for the Rubisco SSUs and for that of the *Cab* genes encoding numerous chlorophyll *a/b*-binding proteins. Moreover, chlorophyll is not produced in the dark because one of the final steps of its biosynthetic pathway, precisely the protochlorophyllide (Pchl_{id}) to chlorophyllide (Chl_{id}) reduction, is carried out by the enzyme Pchl_{id} oxidoreductase (POR) which, in flowering plants, has become light dependent. As a consequence, in dark-grown (etiolated) seedlings of angiosperms, peculiar organelles, named 'etioplasts', originate from proplastids in cells that would become green in the presence of light.

Etioplasts

Etioplasts, which are the chloroplast counterparts in darkness, can be formed in nature during the first phase of plantlet growth, before the emergence from soil. An inner membrane system very different from the thylakoid develops in etioplasts

(Figure 4). Most membranes have a tubular arrangement and aggregate in a tridimensional semi-crystalline network of interconnected tubules, defined 'prolamellar body', from which some lamellar membranes (prothylakoids) extend. The prolamellar body membranes contain the POR associated with Pchl_a and NADPH to form a stable ternary complex, and are particularly rich in MGDG, which favors the tubular arrangement due to its cone-shaped molecular configuration.

Etioplasts exposed to light convert to chloroplasts. The first event of this greening process is the Pchl_a reduction that the photo-activated POR carries out by using the NADPH of the ternary complex. Successively, the etioplast membranes

Figure 4 TEM micrograph of an etioplast from a dark-grown bean cotyledon. The inner tubular membranes are arranged in a semi-crystalline prolamellar body (pb) from which lamellar prothylakoids (pt) extend. Scale = 1 μ m.

rearrange to form primary thylakoids and then a massive synthesis *de novo* of chlorophylls and membranes leads to the formation of the well-organized and photosynthetically competent chloroplast.

Plastids

The chloroplast belongs to the organellar class of plastids. In lower photoautotroph organisms, such as algae, which do not possess cell types with very distinct functions, the photosynthetic chloroplast has remained the sole kind of plastid. On the contrary, in terrestrial plants, which evolved highly specialized tissues and organs, different kinds of plastids with specific structures and functions arose from the original chloroplast. In these plants, the class of plastids, besides the green chloroplasts, includes uncolored amyloplasts, whose function is to store large amounts of starch (Figure 5) and yellow-red-brown chromoplasts which synthesize a lot of carotenoids (Figure 5) and have attractive functions. Apart from the lack of thylakoids, these nonphotosynthesizing plastids share common characteristics with the chloroplasts, like the envelope membranes, the prokaryotic DNA and the 70S ribosomes. Furthermore, they maintain several biosynthetic pathways carried out by enzymes inserted in the stroma or bound to the envelope, such as those of fatty acids and terpenoids.

All the plastids can differentiate from proplastids. However, the possibility also exists that a plastid derives from the conversion of another kind of plastid, according to the

Figure 5 The cyclic model of plastid interconversions. The amyloplast from a cell of *Raphanus* hypocotyl contains large starch grains (S). Globular (arrow) and crystalline (double arrow) carotenoid masses are inserted in the chromoplast from a cell of *Ranunculus* petal. Chloroplast and proplastid are from a mesophyll cell and a basal meristem cell of a maize leaf, respectively. Scale = 1 μ m.

'cyclic model' (Figure 5) proposed already by Schimper at the end of 1800. These reversible plastid interconversions depend on cell-developmental programs as well as on endogenous (hormones and nutrients) or environmental (light and temperature) signals. Only the chromoplasts (named gerontoplasts) derived from chloroplast degeneration during a green tissue senescence cannot undergo further conversion.

Glossary

Calvin–Benson cycle A series of enzymatic reactions in the stromal phase of chloroplasts in which reduced nicotinamide adenine dinucleotide phosphate (NADPH) and adenosine triphosphate (ATP) produced by the light reactions of photosynthesis are consumed to fix CO₂ and form precursors of sugars. Each cycle consumes three ATP and two NADPH molecules and fixes one molecule of CO₂, and the intermediates of the cycle are regenerated.

Glutathione–ascorbate cycle Metabolic pathway that detoxifies hydrogen peroxide (H₂O₂), which is a reactive-oxygen species. In this cycle, ascorbate and glutathione are regenerated and net electron flow is from NADPH to H₂O₂.

Light-harvesting system Antenna system of PSII or PSI consisting of light-harvesting proteins with bound chlorophyll, carotenoid, and lipid molecules, which captures light energy and transfers it to the reaction centers of the two photosystems for the photochemical reactions.

Pasteur effect Shortage of ATP leads to the stimulation of the breakdown of sugars (glycolysis) with

concomitant production of reducing equivalents such as NADH.

Q-cycle Upon oxidation of PQH₂ by the Cytb₆f complex at the Q_o site, two electrons are released. One electron is transferred through a high-potential chain to Cyt_f, whereas the other is transferred through a low-potential chain to two cytochromes within Cytb₆f, and finally to a quinone or semiquinone molecule at the Q_i site. In this way, four protons are pumped into the lumen per two electrons transferred through the Cytb₆f complex.

Quinone Small molecule acting as an electron carrier which can exist in oxidized (PQ) or reduced form (PQH₂).

Retrograde signaling Upon chloroplast dysfunction or plastid-developmental arrest, signals are generated within the chloroplast that are sensed and lead to the activation of a signaling chain from the chloroplast to the nucleus where expression of specific genes is altered in response to the chloroplast signals.

Singlet oxygen A highly reactive form of oxygen formed upon charge recombination within the PSII reaction center or through photosensitization of porphyrins.

Introduction

A remarkable feature of plant and algal cells is the presence of three genetic systems located in the nucleus, chloroplast, and mitochondria, which are autonomous but need to be coordinated for proper functioning and regulation of cellular metabolism. Although the majority of chloroplast proteins is encoded by nuclear genes and the plastid genome has a modest size, the chloroplast can also influence nuclear gene activity under various stress conditions that affect the photosynthetic apparatus. In land plants and algae, the photosynthetic system uses solar energy to convert water and carbon dioxide into sugars with concomitant oxygen evolution. The primary events of photosynthesis occur in the thylakoids, an internal membrane system within chloroplasts consisting of appressed membranes called ‘grana’ and of ‘stromal lamellae’ (Figure 1). The photosynthetic electron transport chain consists of several multicomponent complexes, including proteins and pigments, which are embedded in the thylakoid membranes. At one end of the chain, photosystem II (PSII) uses the light excitation energy absorbed by its light-harvesting system (LHCII) to photo-oxidize a chlorophyll dimer within the PSII reaction center. This event creates a very powerful oxidant capable of splitting water with the concomitant release of protons in the thylakoid lumen and the transfer of electrons to the acceptors of PSII, the quinones Q_A and Q_B, and subsequently to the plastoquinone pool. The electrons are then transferred to

the cytochrome *b₆f* complex (Cytb₆f), which pumps protons into the thylakoid lumen through the Q-cycle and transfers the electrons further to plastocyanin. This soluble protein in the thylakoid lumen acts as an electron carrier between Cytb₆f and PSI. This complex is capable of using light energy captured by its light-harvesting system (LHCI) to induce a charge separation across the membrane, resulting in the oxidation of plastocyanin and the reduction of ferredoxin on the stromal side of PSI and the subsequent reduction of nicotinamide adenine dinucleotide phosphate (NADP⁺) to reduced nicotinamide adenine dinucleotide phosphate (NADPH). This linear photosynthetic electron flow is coupled with proton translocation across the thylakoid membrane and the resulting proton gradient is used by the adenosine triphosphate (ATP) synthase to produce ATP. Both ATP and NADPH are used for driving the Calvin–Benson cycle in the soluble phase of the chloroplast, called stroma, which results in CO₂ fixation and in the formation of sugars.

Although PSII and LHCII are located in the grana, PSI and the ATP synthase are located mainly in the stromal regions and also in the end membranes and margins of the grana. This is due to the fact that both PSI and the ATP synthase contain bulky stromal domains that do not fit between the tightly packed grana stacks.

The different complexes of the photosynthetic electron transport chain have been studied intensively and spectacular advances have been achieved in the structure determination of

Figure 1 Photosynthetic electron transport chain. Light energy absorbed by the light-harvesting system of photosystem II (LHCII) is directed to the reaction center of PSII and used to induce charge separations across the thylakoid membrane followed by extraction of electrons from water, which are subsequently transferred to the plastoquinone pool and the *Cytb₆f* complex. The electrons are further transferred to plastocyanin and to PSI. The latter functions as a light-driven plastocyanin–ferredoxin oxidoreductase. The photochemical water oxidation releases two protons in the lumen and injects two electrons in the electron transport chain, which are used to reduce one plastoquinone molecule. Oxidation of PQH₂ by the *Cytb₆f* complex and operation of its proton pump leads to the further release of four protons in the lumen and, thus, to a total of six protons per two electrons transferred. As 2 electrons are required for the reduction of NADP⁺ and 14 protons are consumed by the ATP synthase to produce three ATP, this leads to an ATP/NADPH ratio of 9/7. Thus, linear electron flow is insufficient for reaching an ATP/NADPH ratio of 1.5 required for the operation of the Calvin cycle. The remaining ATP can be generated through cyclic electron flow in which reduced ferredoxin transfers electrons back to the plastoquinone pool or directly to the *Cytb₆f* complex. In this mode, only ATP is produced. Reducing equivalents can also be transferred to the plastoquinone pool through the chlororespiratory chain. PSII and LHCII are localized in the grana regions, while PSI and ATP synthase are found mostly in the stroma lamellae.

these complexes. PSII, LHCII, *Cytb₆f*, PSI, and ATP synthase have been crystallized and their atomic structure determined. Although we know a great deal about the individual complexes and their structure–function relationship, less is known on how electron flow is regulated and how the redox state of individual components of the photosynthetic electron transport chain influences signaling events within the chloroplast. Two key components in chloroplast redox signaling are the plastoquinone pool and the ferredoxin/ thioredoxin system.

Electron Flow Pathways in the Chloroplast

According to recent estimates, linear electron flow in plants leads to an ATP:NADPH ratio of 9/7, which is below the value of 1.5 required for the operation of the Calvin–Benson cycle (Figure 1). The additional ATP must be provided by another pathway called cyclic electron flow in which reduced ferredoxin transfers its electrons back to the plastoquinone pool or to *Cytb₆f*. In this pathway, two protons are pumped across the thylakoid membrane for each cycling electron without generating reducing power. Hence, the ATP/NADPH ratio can be finely tuned through adjustment of the relative levels of linear and cyclic electron flow to match changing metabolic demands. Alternatively, in a pathway called ‘pseudocyclic electron flow’, molecular oxygen can act as electron acceptor instead of NADP⁺. In addition to these three pathways, the chlororespiratory chain feeds reducing power from the stromal phase into the plastoquinone pool and can, therefore, also modify the redox state of the plastoquinone pool.

The redox poise of the photosynthetic electron transport chain is important for its proper functioning. Both complete reduction and complete oxidation of this chain would lead to

an arrest of electron flow, because in the first case, there is no place for the electron to move to, except for reacting with oxygen, and in the second case, no electrons are available. Hence, the system attempts to maintain a redox poise which, however, can be profoundly affected by environmental factors such as temperature and the limited availability of CO₂, water, and nutrients. Many of these changes lead to a decrease in the activity of the Calvin–Benson cycle which, in turn, leads to an over-reduction of the electron transport chain and to the generation of reactive-oxygen species (ROSs). These ROSs may cause oxidative damage under extreme conditions but are usually detoxified by an efficient plastid-scavenging system, including superoxide dismutase, ascorbate peroxidase, and the glutathione–ascorbate cycle. Signaling mechanisms that connect photosynthetic electron flow with gene expression include reversible changes in redox poise that occur either at the level of the plastoquinone pool or of the ferredoxin/ thioredoxin system at the acceptor side of PSI.

Redox State of Plastoquinone Pool and Chloroplast Signaling

The plastoquinone pool plays a key role in photosynthetic electron transfer. Its redox state depends on the relative activities of PSII and PSI. Because the light-harvesting systems of these two photosystems have different light-absorption properties, the excitation energy transferred to the PSII and PSI reaction centers varies when the quality of the incident light changes. In turn, these changes alter the redox state of the plastoquinone pool. Thus, excess stimulation of PSII relative to PSI leads to a reduction of the plastoquinone pool, whereas excess stimulation of PSI relative to PSII leads to its oxidation.

Changes in the redox state of the plastoquinone pool act as a read-out of any imbalance in the activities of the two photosystems and are sensed by a signaling system that corrects the imbalance both in the short term and in the long term, and thereby restores an optimal photosynthetic yield especially under low-light conditions.

Short-Term Response: State Transitions

A typical short-term response that occurs within minutes is state transition, a process whereby any imbalance in the activities of PSII and PSI resulting from changes in light or metabolic conditions is compensated by a change in the size of the antennae of PSII and PSI. In this way, the two serially connected photosystems function at the same rate and, thus, ensure an optimal photosynthetic yield, especially under low irradiance (Figure 2). When the activity of PSII exceeds that of PSI, the redox state of the plastoquinone pool is more reduced and binding of plastoquinol, the reduced form of plastoquinone, to the Q_o site of $Cytb_6f$ leads to the activation of a protein kinase that phosphorylates a portion of LHCII. The $Cytb_6f$ complex is essential for this activation as mutants deficient in $Cytb_6f$ are unable to phosphorylate LHCII. This phosphorylation causes the release of the mobile portion of LHCII from PSII and favors its binding to PSI, thereby increasing the cross section of the PSI antenna at the expense of the light-harvesting system of PSII. This state is called state 2. The process is reversible as excess stimulation of PSI relative to PSII leads to the oxidation of the plastoquinone

pool and to the inactivation of the kinase which is followed by dephosphorylation of LHCII and its return to PSII. This state is called state 1 (Figure 2).

In the green unicellular alga *Chlamydomonas*, as much as 80% of LHCII is mobile, whereas in land plants only 15–20% of LHCII is mobile during state transitions. This difference can be correlated with the fact that the major function of state transitions in *Chlamydomonas* is to adjust the ATP level to cellular demands. In this alga, a decrease in the amount of ATP induces a transition from state 1 to state 2. Lower ATP levels induce glycolysis through the Pasteur effect and the reducing power generated is transferred through the chlororespiratory chain to the plastoquinone pool, a process that leads to the reduction of this pool and to the activation of the LHCII kinase. In *Chlamydomonas*, transition from state 1 to state 2 is accompanied by a switch from linear to cyclic electron transport in which most of the PSII is disconnected from the other components of the electron transport chain (Figure 2). Another remarkable feature is that state transitions are associated with a remodeling of thylakoid membranes. Major rearrangements occur in these membranes with breakage of bridges between the grana stacks and fusion events.

Both the kinase and phosphatase involved in state transitions have been identified. The kinase Stt7/STN7 is a thylakoid membrane protein associated with $Cytb_6f$ and specifically required for the phosphorylation of LHCII under state 2 conditions. It is well conserved in all eukaryotic organisms performing oxygenic photosynthesis. It is present in vastly substoichiometric amounts relative to $Cytb_6f$, indicating that it must act in catalytic amounts. In its absence, the photosynthetic apparatus is locked in state 1. The TAP38/PPH1 phosphatase is specifically required for the dephosphorylation of LHCII in land plants and mainly associated with the stromal lamellae of thylakoid membranes. Loss of TAP38/PPH1 leads to a persistent state 2 with phosphorylated LHCII and an increased size of the PSI antenna. Thus, the phosphorylation status of LHCII and the control of state transitions are determined specifically by the kinase phosphatase pair STN7 and TAP38/PPH1.

Figure 2 Scheme of state transitions. This process balances the light excitation energy between PSII and PSI upon changes in the spectral composition of light, and thereby ensures an optimal photosynthetic rate. During a state 1 to state 2 transition, excess stimulation of PSII leads to the reduction of the plastoquinone pool that favors docking of plastoquinol (PQH_2) to the Q_o site of $Cytb_6f$. This event activates the LHCII kinase (probably Stt7/STN7), which phosphorylates the mobile portion of LHCII leading to its detachment from PSII and to its binding to PSI (state 2). Preferential stimulation of PSI oxidizes the plastoquinone pool and inactivates the LHCII kinase. Dephosphorylation of LHCII by the phosphatase PPH1/TAP38 is followed by its return to PSII (state 1). In *Chlamydomonas* transition from state 1 to state 2 is accompanied by a switch from linear electron flow (LEF) to cyclic electron flow (CEF), which favors mainly ATP synthesis.

Long-Term Response

Although state transitions represent a short-term response, changes in the redox state of the plastoquinone pool also trigger a long-term response, which occurs in the range of hours or days. Continued stimulation of PSII relative to PSI will in the long term lead to a compensatory response with an increase in the level of PSI to restore the balance between the two photosystems. This long-term response can also be followed by an increase in the ratio between chlorophyll *a* (Chl *a*) and Chl *b* due to the fact that PSI contains less Chl *b* than PSII. Because the long-term response also involves nuclear genes besides chloroplast genes, this implies that the changes in the redox state of the plastoquinone pool are sensed by the nucleus through a retrograde signaling chain. The components of this chain are still largely unknown except for the Stt7/STN7 kinase which is involved both in the long- and short-term responses. Mutants lacking STN7 are unable to adjust the photosystem stoichiometry upon changes in light conditions. The long- and short-term signaling pathways appear to diverge at, or immediately downstream of STN7. Comparison between different

organisms reveals that the redox state of the plastoquinone pool regulates expression of the nuclear LHCII genes either at the transcriptional or posttranscriptional level.

Chloroplast Kinase Network

Besides the Stt7/STN7 kinase, other chloroplast protein kinases have been identified. The Stt7/STN7 kinase is structurally related to Stt1/STN8, another thylakoid protein kinase that is specifically required for the phosphorylation of the PSII core proteins D1, D2, and CP43. Both kinases are phosphorylated under state two conditions and the phosphorylation of Stt1 is dependent on Stt7, suggesting the existence of a chloroplast protein kinase cascade. Mutants of *Arabidopsis* deficient in both STN7 and STN8 are nearly fully deficient in thylakoid protein phosphorylation and display a significant decrease in fitness when grown under changing light conditions or in field tests (Figure 3).

Phosphorylation of PSII and LHCII proteins has been proposed to play a role in the folding of thylakoid membranes through charge repulsion. The availability of mutants of *Arabidopsis* lacking either STN7 or STN8 has provided new tools for examining this question. It appears that loss of PSII core protein phosphorylation leads to marked changes in membrane folding with a significant increase in grana size. By contrast, loss of LHCII phosphorylation does not cause any detectable changes in thylakoid membrane organization. Thus, PSII core protein phosphorylation appears to be more important for shaping the grana than LHCII phosphorylation.

The TAK1 protein kinase of *Arabidopsis*, which forms a small family together with two other similar kinases, has also been proposed to be involved in state transitions based on the observation that lines deficient in TAK1 show diminished LHCII phosphorylation and a partial deficiency in state transitions. This kinase appears to be associated with *Cytb₆f* and PSII but its precise role is still unknown.

In view of the endosymbiotic origin of chloroplasts, one might expect to find conserved bacterial signaling components in plastids. Two-component signal transduction is widespread in prokaryotes and includes a sensor kinase and a response regulator that sense specific environmental cues and trigger appropriate responses mostly at the transcriptional level. A sensor-like kinase-dubbed chloroplast kinase network (CSK) was identified in *Arabidopsis* based on its sequence similarity to corresponding bacterial proteins. Chloroplast transcript accumulation was changed in CSK knockout lines indicating that CSK affects plastid gene expression either directly or indirectly. Moreover, the typical increase in the chl *a*/chl *b* ratio, which occurs under prolonged stimulation of PSII, was abolished in the *csk* mutants. Whether CSK acts as a redox regulatory coupling system between photosynthetic electron transport and chloroplast gene expression remains to be proven.

Another protein kinase implicated in redox-mediated regulation of plastid gene expression is the casein kinase CK2 α that is associated with the plastid RNA polymerase and known to phosphorylate proteins involved in transcriptional and post-transcriptional regulation. Interestingly, the sequence of one phosphorylation site of STN7 conforms to the CK2 α substrate consensus raising the possibility that CK2 α could be involved in the phosphorylation of LHCII through the STN7 kinase. The picture that emerges from these studies is a complex chloroplast kinase and phosphatase signaling network which is involved in both short- and long-term acclimation in response to changing environmental conditions (Figure 3).

Ferredoxin/Thioredoxin and Chloroplast Signaling

Besides the redox state of the plastoquinone pool, that of the ferredoxin/thioredoxin system comprised of ferredoxin, thioredoxin and ferredoxin–thioredoxin reductase also plays a central role in chloroplast signaling. This system is involved in an

Figure 3 Thylakoid protein kinase network. The plastoquinone redox state depends on light quality and quantity, ATP, and CO₂ levels, and modulates the activity of the Stt7/STN7 and Stt1/STN8 kinases required for the phosphorylation of LHCII and PSII, respectively. It may also act on CSK. Activation of the Stt7/STN7 kinase requires a close interaction with the Cytb₆f complex. Phosphorylated LHCII moves from PSII to PSI. Dephosphorylation is mediated by the phosphatase TAP38/ PPH1. The redox state of Trx also influences the activity of Stt7/STN7. The proposed action of CK2 α on Stt7/STN7 and of CSK on chloroplast gene expression is still tentative and will need further experimental support. Besides its role in short-term acclimation, STN7 is also involved in the long-term response (LTR). TAK1 may also contribute to state transitions but its exact role is not known. Protein kinases are highlighted in orange.

extensive SH-group redox regulation and is known to link light to the activity of enzymes in the chloroplast stroma. In their light-induced reduced state, thioredoxins are implicated through disulfide bond reduction in the activation of numerous enzymes functional in biosynthesis. In other cases, the reduction of disulfide bonds leads to the inactivation of enzymes involved in carbohydrate degradation and their activation in the dark occurs through oxidation of the thiol groups. This also appears to hold for lumen proteins that are oxidatively activated in the light. In this respect, the case of Stt7/STN7 is particularly interesting. This kinase, known to be inactivated under high light, is a transmembrane protein with its catalytic domain on the stromal side and the N-terminal end on the lumen side, with two conserved Cys that are critical for the activity of the kinase and likely candidates for targets of thioredoxin. However, thioredoxins are localized on the stromal side of the thylakoid membrane, whereas the target Cys residues are on the lumen side. One possibility is that the redox signal from thioredoxin is shuttled through the membrane by the CcdA and Hcf164 proteins known to transduce thiol-reducing equivalents across the thylakoid membrane.

The reversible changes in redox state of the ferredoxin/thioredoxin system operate at several levels of gene expression, including both transcriptional and posttranscriptional steps. In *Chlamydomonas*, a redox-responsive multiprotein complex binding to the 5'-untranslated region of chloroplast messenger RNA plays a role in the light-induced activation of translation initiation. Other steps in chloroplast gene expression such as RNA degradation, RNA splicing, and translation elongation also appear to be redox modulated.

Retrograde Signaling Pathways

Gun Mutants

Plastid-to-nucleus retrograde signaling is triggered by plastid dysfunction or plastid-developmental arrest and refers to signaling initiated in the chloroplast, which is sensed by the nucleus and leads to altered gene expression. Thousands of nuclear genes in *Arabidopsis* can be affected through these pathways. Several different retrograde signaling chains have been identified which are triggered by inhibition of chloroplast gene expression, perturbations in the tetrapyrrole pathway, and changes in the redox state of the photosynthetic electron transport chain or stress conditions that lead to the formation of ROS. In all these cases, expression of the LHCII gene and of other nuclear genes involved in photosynthesis is decreased during these perturbations. A genetic screen for mutants in which LHCII expression is partially restored has yielded *gun* (genome uncoupled) mutants. Most of these mutants are deficient in components involved in tetrapyrrole biosynthesis, suggesting that tetrapyrroles or their regulators are involved in retrograde signaling. These different retrograde signaling chains appear to be integrated upstream of GUN1, a chloroplast protein associated with the chloroplast nucleoid which comprises the plastid DNA and its associated proteins. The components downstream of GUN1 are still unknown except for the ABI4

transcription factor which has been proposed to mediate repression of nuclear genes upon activation of the retrograde signaling chain.

ROS Signaling: The Case of Singlet Oxygen

ROSs are generated as an inevitable consequence of the multiple photosynthetic electron transfer reactions. They can cause oxidative damage and elicit stress responses. Several chemically distinct ROSs are produced, including hydrogen peroxide and superoxide anion radical generated as a result of the reduction of oxygen at PSI and singlet oxygen produced in PSII reaction centers. Because these ROSs are usually produced simultaneously, it has been difficult to determine which ROS is involved in a specific stress response. This problem could be circumvented through the use of the *flu* mutant of *Arabidopsis*. This mutant accumulates protochlorophyllide, a precursor of chlorophyll in the dark, which is a potent photosensitizer. Upon illumination, this compound generates singlet oxygen. After a transfer from the dark to the light, growth of mature *flu* mutant plants is arrested while *flu* seedlings bleach and die. At first sight, this suggests that plants are damaged due to the toxic levels of singlet oxygen. However, further genetic studies revealed that inactivation of the *Executer 1* gene is sufficient for abolishing the stress response caused by the release of singlet oxygen. Thus, it is not the ROS generated during the stress response which causes damage. Instead, a genetically determined stress response program is activated through the *Executer 1* protein after release and perception of singlet oxygen by the plant that subsequently leads to seedling lethality and growth inhibition of mature plants.

Glossary

HMG-CoA reductase 3-Hydroxy-3-methylglutaryl coenzyme A reductase, a rate-limiting enzyme of cholesterol biosynthesis.

Scap SREBP cleavage activating protein. Scap is required for the transport of SREBP from the endoplasmic reticulum to the Golgi.

SREBP Sterol regulatory element binding protein, a transcription factor that is proteolytically processed before entering the nucleus and binding to a *cis* element on the DNA, termed sterol regulatory element.

Statins A class of drugs that inhibit the activity of HMG-CoA reductase.

Properties of Cholesterol

Cholesterol is a cyclic hydrocarbon that can be esterified with a fatty acid to form a cholesteryl ester. Both cholesterol and cholesteryl esters are lipids and are essentially insoluble in aqueous solution but soluble in organic solvents. Excess cholesterol esters are stored as lipid droplets within the cytosol. Such droplets are prevalent in steroidogenic tissues where they serve as precursors of the steroid hormones. In eukaryotic cells, cholesterol is solubilized as a result of its interaction either with membrane phospholipids or with phospholipids and bile acid micelles in the gall bladder. In blood, cholesterol and cholesterol esters are solubilized within lipoprotein complexes. These lipoproteins, which include low-density lipoprotein (LDL), very low density lipoprotein (VLDL), chylomicrons, and high-density lipoprotein (HDL), function to transport insoluble lipids around the body.

Functions of Cholesterol

Membrane Structure

Cholesterol is absent from prokaryotic cells. However, cholesterol plays an essential structural role in maintaining the fluidity of eukaryotic cell membranes. Cholesterol is not equally distributed in all membranes; the membranes of mitochondria, peroxisomes, and endoplasmic reticulum are cholesterol poor, whereas the plasma membrane is enriched in the sterol. However, the concentration of cholesterol varies significantly even within the plasma membrane; it is highly enriched in two specialized areas termed lipid rafts and caveolae. Since many receptors are localized to these cholesterol- and sphingomyelin-rich domains, it has been suggested that lipid rafts and caveolae function as signaling gateways into the cell.

Precursor of Signaling Molecules

As shown in [Figure 1](#), cholesterol is a precursor of bile acids, steroid hormones, and oxysterols (oxidized cholesterol). These cholesterol metabolites function to activate specific nuclear receptors that control many metabolic and developmental processes. In addition, intermediates in the cholesterol

biosynthetic pathway are themselves precursors for other critical pathways. For example, 7-dehydrocholesterol is a precursor of vitamin D, and farnesyl diphosphate is a precursor of geranylgeranyl diphosphate, ubiquinone, Heme a, and dolichols ([Figure 1](#)). Although beyond the scope of this article, it is now clear that modification (prenylation) of many proteins by either farnesyl diphosphate or geranylgeranyl diphosphate is critical for cell survival. Thus, hypolipidemic drugs (e.g., statins) that inhibit HMG-CoA reductase activity must be used at doses that result in partial, not total, inhibition of the pathway.

Sources of Cellular Cholesterol

Diet and Lipoproteins

Insects are cholesterol auxotrophs and must obtain cholesterol from the diet. In contrast, other eukaryotes obtain cholesterol from two sources: the diet and endogenous synthesis. Mammals absorb 40–50% of the cholesterol in their diet and transport it to the liver and other tissues in lipoproteins. The plasma lipoproteins bind to cell-surface receptors prior to the delivery of the lipid cargo to the cell. Such receptors include the LDL receptor, SR-B1, SR-A, and CD36. The LDL receptor is expressed on the surface of most cells and plays a particularly important role in cholesterol homeostasis. This transmembrane protein binds cholesterol-rich LDL and facilitates the delivery of cholesterol into the cell via specialized areas on the cell surface called clathrin-coated pits. However, virtually all mammalian cells also synthesize cholesterol ([Figure 1](#)).

Cholesterol Synthesis

There are many reviews on the biosynthesis of cholesterol, possibly in part because work in this area has been extensive and has led to numerous Nobel prizes. All mammalian cells, with the exception of mature red blood cells, utilize more than 30 enzyme reactions and 11 molecules of dioxygen to convert the 2 carbon acetate to the 27 carbon cholesterol via isoprenoid intermediates ([Figure 1](#)). The rate-limiting enzyme in this pathway, HMG-CoA reductase, is the target for many hypolipidemic drugs ([Figure 1](#)). Together, the cholesterol biosynthetic pathway and the LDL receptor pathway provide sufficient

Figure 1 The cholesterol biosynthetic pathway. Selected intermediates (black boxes) and enzymes of the cholesterol synthesis pathway are shown for simplicity. SREBP-2 regulates transcription of genes throughout the pathway, and a few are shown (*italics*). Statins and bisphosphonates inhibit HMG-CoA reductase and farnesyl diphosphate synthase, respectively. Isoprenoids and sterols are precursors for important products, such as ubiquinone, vitamin D, steroids, and bile acids. Modified from Edwards P (2004) In: Lennarz WJ and Lane MD (eds.) *Encyclopedia of Biological Chemistry*, 1st edn., pp. 451–455. Amsterdam: Elsevier.

cholesterol necessary for cell growth and division. These two pathways are coordinately controlled by an exquisite mechanism that senses cellular cholesterol levels. The mechanism involves the generation of three functionally active transcription factors termed sterol regulatory element binding proteins (SREBPs).

Transcriptional control of cholesterol synthesis

There are two SREBP genes, SREBP-1 and SREBP-2. The SREBP-2 gene produces one protein that preferentially activates genes involved in cholesterol homeostasis. In contrast, two proteins, SREBP-1a and SREBP-1c, are produced from the SREBP-1 gene. SREBP-1c preferentially activates genes involved in fatty acid

synthesis. SREBP-1a activates both pathways but is expressed at relatively low levels. Newly synthesized SREBP proteins contain two transmembrane domains that form a hairpin-like structure and anchor the proteins in the endoplasmic reticulum, outside the nucleus (**Figure 2**). If these proteins are anchored to membranes outside the nucleus, how can they function as transcription factors in the nucleus?

The answer came from a series of elegant studies initiated in the laboratory of Goldstein and Brown in Dallas. They showed that generation of nuclear-localized SREBPs requires additional proteins named Insig, Scap, the site 1 protease (S1P), and the site 2 protease (S2P) (**Figure 2**). The roles of these proteins vary; Scap functions both as a cholesterol

Figure 2 Mechanisms involved in the nuclear targeting of SREBP and the altered stability of HMG-CoA reductase. The left side represents conditions where the cholesterol concentration in the cell is low. Under these conditions, SREBP is transported from the endoplasmic reticulum (ER) to the Golgi, where SREBP is cleaved by S1P and S2P. Cleaved SREBP then travels to the nucleus where it binds DNA as a dimer and activates many target genes. For simplicity, only the LDL receptor and HMG-CoA reductase genes are shown. HMG-CoA reductase (HMGCR) protein also accumulates in the ER where it catalyzes the reduction of HMG-CoA to mevalonic acid (MVA). The right side represents conditions where cellular cholesterol levels are higher than normal. Under these cholesterol-rich conditions, Insig binds to Scap/SREBP and inhibits transport to the Golgi and nuclear localization of SREBP. In addition, the rate of degradation of HMG-CoA reductase is increased. Degradation is preceded by the formation of an Insig/HMG-CoA reductase complex. Modified from Edwards P (2004) In: Lennarz WJ and Lane MD (eds.) *Encyclopedia of Biological Chemistry*, 1st edn. Amsterdam: Elsevier.

sensor and as an escort protein to transport SREBP to the Golgi where two proteases cleave SREBPs to release the soluble amino-terminal fragment. The process is also regulated by Insig, which functions to control the exit of Scap/SREBP from the endoplasmic reticulum (Figure 2). In brief, when cells become cholesterol-poor, for example, after addition of a drug that inhibits cholesterol synthesis, the Scap/SREBP-2 heterodimeric complex is transported in coat protein complex II (COPII) vesicles that bud from the endoplasmic reticulum and then fuse with the Golgi (Figure 2). The Golgi contains two resident proteases, S1P and S2P, that sequentially cleave the newly arrived SREBP-2 protein; first S1P cleaves SREBP into two parts by cleaving the hairpin loop in the lumen of the Golgi, then S2P cleaves the protein at a second site within the transmembrane segment to release a soluble amino-terminal domain (Figure 2). This soluble amino-terminal fragment, containing a transcriptional activation domain and a basic helix-loop-helix-leucine zipper DNA-binding domain, migrates to the nucleus where it binds to specific DNA sequences termed sterol response elements (SREs) and activates transcription. SREs have been

identified in the promoters of many genes involved in cholesterol and fatty acid and lipid synthesis. Such genes include HMG-CoA synthase, HMG-CoA reductase, farnesyl diphosphate synthase, squalene synthase, lanosterol synthase, and the LDL receptor (Figure 1). In summary, a transient decrease in cellular cholesterol levels leads to increased levels of transcriptionally active SREBP-2 in the nucleus and activation of genes involved in cholesterol synthesis and uptake of LDL. The net result is a rapid return of the cellular sterol levels to normal.

In contrast, when cells accumulate cholesterol, Scap binds cholesterol and undergoes a conformational change that induces binding of the Scap/SREBP heterodimer complexes to Insig. Since Insig is a resident protein of the endoplasmic reticulum, the Insig/Scap/SREBP-2 complex remains localized to this membrane (Figure 2). Consequently, transport of SREBP-2 to the Golgi and subsequent cleavage and nuclear localization of the protein is blocked. As a result, transcription of genes coding for the LDL receptor and cholesterol synthesis enzymes is low. Such changes in gene expression will prevent or reduce subsequent cholesterol accumulation in the cell.

SREBP-2 proteolytic activation is also suppressed in response to elevated levels of oxysterols, such as 25-hydroxycholesterol. Oxysterols bind to Insig and stimulate Insig to bind Scap, thus retaining the Scap/SREBP-2 complex in the endoplasmic reticulum.

Regulated degradation of HMG-CoA reductase

HMG-CoA reductase catalyzes the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reduction of HMG-CoA to mevalonic acid (MVA in [Figure 2](#)). It is considered to be the rate-limiting enzyme of the cholesterol biosynthetic pathway. Thus, changes in the activity of the enzyme are paralleled by changes in cholesterol synthesis. The activity of the enzyme is regulated by changes in transcription, translation (mechanism unknown), and protein stability.

HMG-CoA reductase contains two domains: an eight-transmembrane spanning region that localizes the protein to the endoplasmic reticulum and a carboxy-terminal domain that projects into the cytosol and contains the catalytic activity ([Figure 2](#)). Degradation of HMG-CoA reductase is regulated, and the half-life (a measure of protein stability) varies at least 10-fold. When cellular cholesterol levels are low, the enzyme is relatively stable (half-life ~ 10 h). Thus, active HMG-CoA reductase enzyme accumulates in the endoplasmic reticulum in response to (1) a slow rate of degradation of the protein and (2) increased transcription and enzyme synthesis ([Figure 2](#)). Since HMG-CoA reductase is the rate-limiting enzyme, the net result is increased cholesterol synthesis.

However, when cellular cholesterol levels increase, the rate of degradation of HMG-CoA reductase protein is enhanced ≥ 10 -fold (half-life < 45 min). HMG-CoA reductase degradation is accelerated when cells accumulate the sterol intermediate 24,25-dihydrolanosterol ([Figure 1](#)) and protein turnover is further stimulated by a nonsterol isoprenoid derived from farnesyl diphosphate. Elevated 24,25-dihydrolanosterol induces binding of HMG-CoA reductase to Insig, which forms a complex with the ubiquitin E3 ligase gp78. Subsequent ubiquitinylation of HMG-CoA reductase by gp78 results in its degradation by the proteasome through a mechanism known as endoplasmic reticulum-associated degradation (ERAD; [Figure 2](#)).

Thus, Insig has a dual role in cholesterol-enriched cells; it interacts with HMG-CoA reductase to promote degradation of the enzyme, and with Scap to retain SREBP-2 in the endoplasmic reticulum ([Figure 2](#)). These interactions depend on the partially conserved sterol-sensing domains identified in both HMG-CoA reductase and Scap. In summary, cholesterol-loaded cells have low levels of HMG-CoA reductase protein (and hence low rates of cholesterol synthesis) because (1) the enzyme is rapidly degraded and (2) transcription of the gene is low as a result of the retention of SREBP-2 in the endoplasmic reticulum ([Figure 2](#), right side). Such changes will minimize subsequent cholesterol accumulation in the cell.

Effect of Mutations in the Cholesterol Synthetic Pathway

Mutations in the cholesterol synthetic pathway are rare because they are usually incompatible with life. Mutations in genes encoding mevalonic acid kinase (an early enzyme in the

pathway) and 7-dehydrocholesterol (a late enzyme in the pathway) result in mevalonic acid urea and Smith-Lemli-Opitz syndrome, respectively. It should be emphasized that patients with mevalonic acid urea have residual mevalonic acid kinase activity, sufficient to provide isoprenoid intermediates that are necessary for cell survival. Indeed, a complete blockage of early steps in cholesterol biosynthesis leads to embryonic death. Patients with mutations in genes that result in impaired cholesterol synthesis exhibit various neurological dysfunctions. Such observations emphasize the importance of cholesterol to the neurological system.

Inhibitors of Cholesterol Synthesis: Treatment for Hyperlipidemia and Osteoporosis

Statins

Elevated LDL cholesterol levels (hypercholesterolemia) are relatively common in the West. Hypercholesterolemia is associated with the development of atherosclerosis, coronary heart disease, myocardial infarction, and increased mortality. One class of drugs, referred to collectively as statins, has proved to be extremely effective in lowering plasma LDL levels and in reducing the progression of atherosclerosis and clinically associated problems.

Mevinolin is a fungal metabolite that is structurally related to HMG-CoA. It was originally discovered in 1976 by Akira Endo in Japan and shown to be a potent competitive inhibitor of HMG-CoA reductase; it binds to the enzyme with a $K_i \sim 10^{-9}$ M, compared to a $K_m \sim 10^{-6}$ M for the natural substrate HMG-CoA. Subsequent studies by many investigators led to the identification of a number of natural and synthetic compounds that also inhibit the enzymatic activity of HMG-CoA reductase. These drugs are collectively known as statins. When taken orally, these drugs are absorbed and targeted to the liver where they bind and partially inhibit HMG-CoA reductase and cholesterol synthesis. The liver cells sense this decrease in newly synthesized cholesterol and respond by enhancing the cleavage and nuclear localization of SREBP-2 ([Figure 2](#)). As a result, expression of a number of genes, including the LDL receptor and HMG-CoA reductase, is increased. The increased expression of the LDL receptor protein on the hepatocyte cell surface results in increased clearance of cholesterol-rich LDL from the plasma into the liver. This is the molecular basis for the clinical effects of the drug. Fortunately, the liver does not become loaded with lipid because it converts the LDL-derived cholesterol to bile acids and excretes the latter in the bile. In summary, oral administration of statins results in an increased rate of removal of LDL from the blood and a decline in blood LDL cholesterol levels. Such a change has been shown to reduce both the progression of coronary atherosclerosis and the incidence of myocardial infarction and death.

Bisphosphonates

Bisphosphonates are potent inhibitors of bone resorption and are used widely to treat osteoporosis. After absorption, these drugs are targeted to bone, where they are taken up by osteoclasts, the bone-resorbing cells. The nitrogen-containing class of bisphosphonates inhibits farnesyl diphosphate synthase and

isoprenoid synthesis (Figure 1). As a result, the osteoclasts undergo apoptosis and bone resorption is attenuated.

Chromatin: Methyl-CpG-Binding Proteins

D G Skalnik, Indiana University, Indianapolis, IN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

CpG island Region of DNA containing a cluster of unmethylated CpG dinucleotides, often found near promoters of actively expressed genes.

Epigenetics Heritable patterns of gene expression that occur in the absence of altered DNA sequence.

Euchromatin Open form of chromatin associated with transcriptionally active genes.

Genomic imprinting Phenomenon whereby maternally derived and paternally derived alleles of a gene exhibit distinct expression patterns as a result of distinct epigenetic modifications established during gametogenesis.

Heterochromatin Highly compact form of transcriptionally inactive chromatin.

The development of multicellular organisms requires the generation of a variety of terminally differentiated cell types from a common set of totipotent stem cells. Integral to this process is the phenomenon of cell memory (e.g., a liver cell gives rise to progeny liver cells upon cell division, rather than kidney or spleen cells). At the molecular level, cell memory derives from distinct patterns of gene expression that are correlated with each type of cell lineage. However, nearly all somatic cells in a multicellular organism contain the same genome. The term epigenetics refers to heritable patterns of gene expression that occur in the absence of altered DNA sequence, and represents the underlying molecular mechanism for cell memory. The CpG dinucleotide represents an important regulatory component of mammalian genomes. The cytosine of this dinucleotide serves as the target of DNA methyltransferases, which catalyze the formation of 5-methylcytosine, a critical epigenetic modification of DNA. Methylated DNA is associated with transcriptionally inactive genes and is generally tightly packaged as heterochromatin, while actively expressed genes are generally hypomethylated and present in a more open euchromatin configuration. Methyl-CpG-binding proteins contribute to both the formation of heterochromatin and the repression of transcription.

Epigenetic Regulation of Gene Expression

The DNA of higher eukaryotes is found tightly associated with proteins *in vivo*. In fact, at least 50% of the mass of a chromosome is contributed by proteins. Although originally thought to provide primarily a packaging function, it is now appreciated that chromatin structure is highly dynamic and plays a critical function in the epigenetic regulation of gene expression. It is necessary to understand the nature of chromatin structure to appreciate the function of methyl-CpG-binding proteins.

Nucleosomes

The primary level of chromatin structure is the nucleosome, in which a DNA double helix is wrapped twice around a core

octamer of eight histone protein molecules (two copies each of histone H2A, H2B, H3, and H4). Nucleosomes are separated by short linkers of DNA, and 200 base pairs of DNA are present in each nucleosome repeat. Chromatin in this configuration is referred to as a 'bead-on-a-string' structure, or euchromatin, and can be transcriptionally active. Additional packaging of nucleosomes into a 30-nm helical array is found in heterochromatin, which is transcriptionally inactive, and is also tightly associated with another species of histone (H1).

Histone Code

Determination of the structure of the nucleosome revealed that the amino terminus of each histone molecule extends away from the octamer core. These histone tails are sites of covalent modification, such as phosphorylation, acetylation, and methylation. At least three-dozen distinct sites of covalent modifications within histone tails have been identified, and many of these are associated specifically with either euchromatin or heterochromatin (Figure 1). The sum of histone modifications found in chromatin is referred to as the histone code, and provides important regulatory information with respect to chromatin structure and ultimately gene expression. For example, acetylated histones are found preferentially in euchromatin. The net acetylation state of a specific region of chromatin is the result of balance between the action of histone acetyltransferases (HATs) and histone deacetylases (HDACs). Similarly, methylated lysine 4 of histone H3 is found in euchromatin, while heterochromatin preferentially contains histone H3 methylated at the lysine 9 position. Lysine residues in histone proteins can be mono-, di-, or trimethylated. Posttranslationally modified histone molecules serve as binding sites for effector proteins implicated in the control of chromatin structure. For example, methylated lysine 9 of histone H3 serves as a binding site for the heterochromatin-associated protein HP1, which recruits a histone methyltransferase to the chromatin. This leads to the methylation of adjacent histone H3-lysine 9 residues, formation of additional HP1-binding sites, and spreading of the heterochromatin configuration.

For each species of histone protein, the amino acid residue, position, and type of modification are presented. Me, mono-, di-, or trimethylation; P, phosphorylation; Ac, acetylation.

Cytosine Methylation

Another covalent modification associated with heterochromatin and repression of gene expression is cytosine methylation, which occurs in the DNA double helix predominantly in the context of the 5'-CpG-3' dinucleotide (where p denotes the phosphodiester linkage between the cytosine and guanine nucleotides). In mammalian genomes, 75% of CpG motifs are methylated, and these are concentrated in areas of repetitive DNA sequences. This dinucleotide is the target of DNA methyltransferase proteins, which catalyze the addition of a methyl group to the C5 position of the cytosine ring. DNA methyltransferase 1 is the major maintenance methyltransferase. It exhibits high affinity for hemi-methylated DNA (the immediate product of semi-conservative DNA replication), and catalyzes the addition of a methyl group to the CpG cytosines within the newly synthesized DNA strand. DNA methyltransferases 3a and 3b are *de novo* DNA methyltransferases that are responsible for establishing specific patterns of cytosine methylation during gametogenesis and early development. The mechanisms by which appropriate patterns of cytosine methylation are initially established are not well understood.

Functions of Cytosine Methylation

Appropriate patterns of cytosine methylation within DNA are essential for numerous biological processes. This is clearly reflected in the finding that mice lacking DNA methyltransferase gene(s) die prior to or shortly after birth.

Regulation of Gene Expression

As mentioned above, cytosine methylation is associated with heterochromatin and repressed gene expression. As the majority of 5-methylcytosine is found in repetitive DNA elements, this may provide a defense mechanism against expression of parasitic

DNA. Indeed, loss of appropriate cytosine methylation results in the induction of repetitive DNA expression. Maintenance of repetitive elements in heterochromatin configuration may also be important for chromosome stability by preventing homologous recombination between repetitive element sequences.

X-Chromosome Inactivation

X-chromosome inactivation refers to the irreversible inactivation during early embryonic development of one of the X-chromosomes present in each cell of a female. The inactive X-chromosome becomes heavily methylated at CpG motifs and takes on a heterochromatin configuration.

Genomic Imprinting

Distinct patterns of cytosine methylation are established throughout the genome during spermatogenesis and oogenesis, leading to parent-of-origin epigenetic marks that distinguish maternally derived alleles from paternally derived ones. Such genomic imprinting can result in a uni-allelic pattern of gene expression. Genomic imprinting is essential for normal development, as zygotes carrying two sets of paternal or two sets of maternal alleles fail to develop normally, even though they carry an appropriate diploid complement of the DNA genome. To date, 150 mammalian genes have been identified that exhibit genomic imprinting.

Cancer

A large number of DNA mutations in oncogenes and tumor suppressor genes have been identified in cancer cells. More recently, it has been recognized that cancer cells also exhibit epigenetic aberrations, including global cytosine hypomethylation, as well as hypermethylation of CpG motifs, specifically within the promoters of tumor suppressor genes. Pharmacologic modulation of the epigenome represents a novel chemotherapy strategy. For example, inhibition of HDAC enzymes is being utilized to induce expression of inappropriately silenced tumor suppressor genes in cancer patients.

Methyl-CpG-Binding Proteins

The function of methylated CpG motifs is mediated in part by methyl-CpG-binding proteins, which specifically bind to DNA at sites of methyl-CpG and affect transcription rates and local chromatin structure. A small family of proteins share a common DNA-binding domain, the methyl-CpG-binding domain (MBD) (Figure 2).

MeCP2

MeCP2 is the founding member of the MBD protein family. It localizes to heterochromatin *in vivo* and represses transcription via a carboxyl terminus transcriptional repression domain (TRD). MeCP2 also contains an amino terminus MBD DNA-binding domain. One mechanism for MeCP2-mediated

Figure 2 Schematic comparison of the MBD family of proteins. The conserved methyl-CpG-binding domains (MBD) present in each protein are aligned. TRD, transcriptional repression domain.

transcriptional repression appears to be regulation of chromatin structure, as the TRD of MeCP2 interacts with a co-repressor that contains an HDAC. Disruption of the X-chromosome-linked MeCP2 gene in mice leads to premature death, and mutations in the human MeCP2 gene causes Rett syndrome, a progressive neurodegenerative disease found nearly exclusively in girls. Deficiency of MeCP2 in neural cells leads to increased histone acetylation and inappropriate transcription of repetitive DNA elements. The severity of symptoms in Rett syndrome depends on the exact nature of mutation present in the MeCP2 gene (most of which alter the sequence of the MBD or TRD domains), and the mosaic pattern of mutant gene expression resulting from random X-chromosome inactivation.

MBD1

Similar to MeCP2, MBD1 contains an amino terminus MBD DNA-binding domain and a carboxyl terminus TRD, although the TRD exhibits no sequence similarity to the MeCP2 TRD. MBD1 binds methylated DNA targets and represses gene expression. Various isoforms of MBD1 produced by differential RNA splicing additionally contain two or three CXXC domains, a cysteine-rich motif also found in DNA methyltransferase 1, human trithorax (HRX), and CXXC finger protein 1 (CFP1). The CXXC domain constitutes the DNA-binding domain of CFP1, and is responsible for that factor's binding specificity for DNA containing unmethylated CpG motifs. Similarly, HRX also binds unmethylated-CpG motifs, and the third CXXC domain of MBD1 is responsible for this factor's ability to bind unmethylated target sequences and repress transcription. The significance of the CXXC domain for MBD1 function is unclear, as it is not required for binding to sites of methyl-CpG motifs. Mice lacking MBD1 are viable, but suffer from reduced neural differentiation and increased genomic instability.

MBD2 and MBD3

MBD2 and MBD3 are the most structurally related members of the MBD family, sharing 75% similarity over the entire length

Figure 3 Summary of chemical relationships between cytosine, 5-methylcytosine, uracil, and thymidine, including how these species inter-convert *in vivo*. DNMT, DNA methyltransferases.

of MBD3, the shortest member of the family. MBD2 contains an additional 140-amino-acid amino terminus extension. Despite this structural similarity, these MBD proteins exhibit quite dissimilar properties. MBD2 binds to methylated DNA and represses transcription via overlapping MBD and TRD domains. MBD2 interacts with HDAC1, and is a component of the methyl-DNA-binding complex MeCP1. The ability of MBD2 to repress transcription is sensitive to inhibitors of HDAC activity, suggesting a mechanism for cross-talk between cytosine methylation and chromatin structure. Surprisingly, mice lacking the MBD2 gene are viable despite lacking the MeCP1 complex. By contrast, MBD3 contains a divergent MBD domain and fails to interact directly with methylated DNA. However, similar to MeCP2, MBD3 is a component of a co-repressor complex. The importance of MBD3 is illustrated by the finding that mice lacking an MBD3 gene fail to develop to birth.

MBD4

MBD4 is an unusual member of the MBD protein family, as it apparently plays no role in transcriptional repression; rather, it functions as a DNA-repair protein. Cytosine exhibits a propensity to deaminate spontaneously to form uracil (Figure 3). Cells contain DNA repair enzymes (e.g., uracil DNA glycosylase) that recognize a uracil base in DNA as a site of damage, and excise this nucleotide to permit replacement with cytosine. This may explain the presence of thymidine in DNA rather than uracil, as it would be more difficult for a cell to recognize a site of cytosine deamination if uracil were a normal nucleotide used for encoding genetic information in DNA. However, deamination of 5-methylcytosine leads to the formation of thymidine. It is this rate of spontaneous deamination that leads to the relative rarity of the CpG dinucleotide in mammalian genomes (only ~10% of the expected frequency). Conversely, CpG motifs near widely expressed genes are usually unmethylated, and hence avoid this

mutagenic pressure. This is hypothesized to explain the clustering of unmethylated CpG motifs in CpG islands near the promoters of 50% of mammalian genes. The MBD domain of MBD4 binds with highest affinity to methylated CG/TG mismatched sequences, and the protein also contains a glycosylase activity in its carboxyl terminus, which removes the mismatched thymidine base from DNA to permit replacement with cytosine. The biological significance of this enzymatic activity is illustrated by an elevated rate of mutation at CpG motifs and increased tumorigenesis in mice lacking MBD4.

MBD5 and MBD6

Relatively little is known about these widely expressed MBD-containing proteins. However, haplo-insufficiency of MBD5 leads to severe mental retardation in humans.

Cross-Talk between DNA Methylation and Chromatin Structure

The nature of epigenetic modifications associated with transcriptionally active or inactive genomic loci is now well established. Current investigations are focused on the regulation of these modifications. How does a cell choose which regions of DNA to methylate and/or assemble into heterochromatin? Recently, it has become clear that DNA methylation and chromatin structure are highly interdependent epigenetic processes. For example, perturbations of the cellular machinery responsible for nucleosome remodeling or histone modifications also result in aberrations in the pattern of cytosine methylation. Conversely, the association of MBD family members

with chromatin-modifying enzymes (e.g., HDACs) suggests a mechanism whereby cytosine methylation may provide an epigenetic mark that permits targeted recruitment of chromatin-remodeling enzymes to specific genomic loci. Hence, cytosine methylation patterns and the histone code may represent mutually reinforcing processes that lead to the stable maintenance of chromatin packaging and gene expression patterns characteristic of cellular memory.

Glossary

Activator Proteins that enable or enhance the transcription of genes.

Gene-specific factors Proteins whose function is associated with expression of a specific gene or gene family.

General factors Proteins whose function is associated with expression of many and unrelated genes.

Nucleosome The octameric complex of core histone proteins wrapping up 147 bp of DNA; the basic structural unit of eukaryotic chromosomes.

Promoter The DNA sequences through which control of transcription is implemented.

The impacts of nucleosomes and, in particular, nucleosome locations (positioning) on biological functions such as transcription have been subjects of intense interest from the earliest days of nucleosome study. On some eukaryotic promoters, nucleosomes are positioned on regulatory elements when genes are in the inactive state of expression but undergo alteration (remodeling and removal) during transcription activation. Yeast PHO5 and mammalian mouse mammary tumor virus (MMTV) promoters provide well-studied examples of this organizational mode. On genes, such as PET56 and DED1, promoter elements remain largely nucleosome-free regardless of the state of expression of the associated gene. The GAL1–10 genes in the budding yeast *Saccharomyces cerevisiae* demonstrate both types of promoter nucleosome organization, affecting different classes of promoter elements. Furthermore, the promoter chromatin organization on GAL1–10 has been shown to play a key role in transcriptional regulation of these genes.

GAL1–10: Gene Expression and Chromatin Structural Features

GAL1 and GAL10 encode enzymes that function in the conversion of galactose to a glycolytic intermediate, thus allowing galactose to be used as a carbon source for cell growth. Genetic characterization of the GAL genes and dissection of their regulatory mechanisms by Douglas and Hawthorne in the 1960s provided a firm and crucial foundation for the molecular level characterization of GAL1–10 gene expression and its regulation that began in the late 1970s and the analysis of GAL1–10 chromatin structure that began in the mid-1980s.

Expression of GAL1 and GAL10 has a striking carbon source dependence; transcription occurs at extremely high levels in galactose-grown cells but is completely undetectable in cells grown in other carbon sources, such as glucose or glycerol–lactate (gly–lac). Their clear-cut and highly efficient control (the genes transcribed only when the gene products are needed), plus their genetic and biochemical tractability have made GAL1–10 a very useful model system for studies of gene regulation and its relation to nucleosome organization. GAL1–10 regulation occurs mainly at the transcriptional level, involving inputs from DNA sequence (promoter) elements, protein

factors (gene-specific and general), and chromatin structure. In the following discussion, genes are referred to as GAL1, protein factors as Gal1p.

Promoter DNA Elements

GAL1 and GAL10 share a common, ~600-bp intergenic promoter DNA region from which they are co-regulated and divergently transcribed (Figure 1). Within this region lie the most important promoter elements for GAL1–10 expression, the gene-specific upstream activation sequence (UAS_G) elements. As shown by the Ptashne laboratory, these ~17-bp motifs are necessary and sufficient for galactose-dependent transcription; they provide the binding sites for Gal4p, the specific activator of GAL gene transcription. GAL1–10 share four UAS_G elements asymmetrically located between the genes (Figure 1). GAL1 and GAL10 each have their own TATA sequence for binding the general transcription factor, TATA-binding protein (TBP).

Regulatory and Transcription Factors

Major gene-specific factors

Gal4p

The major and required activator for GAL gene expression is Gal4p. In cells growing in galactose, Gal4p activates transcription through a domain located near its carboxy terminus, residues 767–881, while bound to (UAS_G) DNA via a domain located near its amino terminus. DNA binding and transcription activation are separable functions on Gal4p (established by the Ptashne laboratory). Gal4p binds as a homodimer to individual UAS_G elements.

Gal80p

In carbon sources other than galactose, the negative regulator Gal80p binds to the C-terminal activation domain of Gal4p and masks Gal4p activation activity, thus preventing GAL1–10 transcription. Gal80p binds Gal4p quite strongly ($K_d \sim 5$ nM).

Gal3p

In the presence of galactose, the Gal80p-mediated inhibition of Gal4p is relaxed via a Gal3p-dependent process, thus freeing the Gal4p activation domain to activate GAL1–10 transcription.

Figure 1 An outline of GAL1–10 promoter organization and gene regulation. The DNA sequence organization of the promoter region is shown at the center of the figure (DNA), with UAS_G (blue brackets) and TATA boxes (green, boxed T" located to scale along the sequence (gray line). The numbers refer to base pairs from an EcoRI site in the GAL10 gene. The transcription start sites lie at the origins of the two wavy arrows below (GAL10) or above (GAL1) the line. The chromosomal structure of this region in the inactive state of gene expression is shown at the bottom of the figure (Chromosome) with nucleosomes A, B, and C (pink) located at their correct sites on the sequence and the nucleosome-free region in the chromosome indicated by a dashed line (HR). The locations of intrinsic, sequence-specific DNA bends are identified by the symbol $\wedge$. In the topmost portion of the figure (Factors), various factors and complexes known or thought to be involved in regulating and implementing GAL1–10 expression are shown. The GAL-specific expression-enabling factors (3p, Gal3p; 4p, Gal4p) are shown in blue and solid blue arrows designate the reactions that occur in, or are characteristic of, the active (galactose-induced, G) state. Dotted blue arrows indicate the suggested recruitment of complexes by Gal4p during gene activation, such as RNA polymerase II (RNA pol II), including the suppressor of RNA polymerase B subunit (SRB) proteins and the Spt-Ada-Gen5-acetyltransferase (SAGA) complex. The activation domain (AD) of Gal4p is solid blue and the DNA-binding domain is identified (DB). The GAL-specific negative regulator, Gal80p (80p), is shown in red and solid red arrows designate the reactions that occur in, or are characteristic of, the inactive state of gene expression. The association/dissociation reactions between TBP and the GAL1 and GAL10 TATA and the disruption/redeposition reactions of promoter nucleosomes A and B are also designated by solid blue/red arrows, again color-coded to reflect the situation in the active/inactive state of expression. The involvement of Gal4p and Gal80p in the promoter nucleosome disruption/redeposition cycle is indicated by their appearance in parentheses next to the appropriate arrow. Nucleosome C, which also undergoes similar disruption/redeposition behavior to A and B, is not shown in the upper portion of this figure, for simplicity.

Interestingly, the GAL1 gene product, Gal1p, contains a Gal3p-like activity that should make it capable of fulfilling a similar function to Gal3p.

General factors

Factors associated with global processes, notably the general glucose repression system, also participate in GAL1–10 regulation and elements of the RNA polymerase II machinery (cf. SAGA, Mediator, and Swi-Snf) function in GAL1–10 transcription. Genomic studies have identified other galactose-sensitive and Gal4p-regulated genes, but whether they are involved in GAL1–10 regulation remains unknown.

Promoter Chromatin Organization

The promoter of GAL1–10 has a distinctive and functionally suggestive chromatin organization (as first shown in the

Lohr laboratory). Within the intergenic domain, there is a sizable (at least 150 bp), highly accessible stretch of DNA. This corresponds to a nucleosome-free, hypersensitive region (HR, Figure 1). This HR region is present regardless of the state of gene expression, that is, in all carbon sources, and all four UAS_G elements reside well within the region. In the inactive states of gene expression (nongalactose carbon sources), positioned nucleosomes (A–C, Figure 1) bracket the HR region. These promoter nucleosomal regions include the TATA and transcription start sites for each gene. Note that nucleosomes cover the GAL10 TATA and GAL1 start site but bracket the GAL10 start site and GAL1 TATA rather than uniformly covering all of these elements. Whether this is significant is unclear. The coding regions of the genes are also nucleosome covered (not shown).

Just how precisely promoter nucleosomes A–C are positioned remains uncertain but both the HR–nucleosomal

region boundaries and the internucleosomal boundaries are sharp and constant in location. Thus, the UAS_C elements are always nucleosome-free and the adjacent TATA and transcription start sites nucleosome involved. The precision of nucleosome positioning does clearly diminish away from the promoter region (in the coding sequences). As shown by the Lohr laboratory, the DNA regions near the termini of nucleosomes A and B contain strong intrinsic, sequence-dependent DNA bends (Figure 1), which could contribute to the preferential location of these nucleosomes *in vivo*. However, *in vivo* positioning must also involve other features because *in vitro* nucleosome reconstitution of GAL1–10 intergenic region DNA does not produce detectable positioning (shown by the Lohr laboratory). It is likely that the nucleosome-free HR region, which is a constant and unchanging feature of GAL1–10 promoter chromatin, helps position nucleosomes A–C *in vivo*, perhaps by acting as a boundary. HR region DNA readily forms nucleosomes *in vitro*, so its nucleosome-free nature *in vivo* must reflect specific cellular nucleosome-exclusion mechanisms, perhaps involving higher-order chromosomal features. What these might be remains unknown.

This promoter chromatin organization – accessible HR, flanking nucleosomes – has been established by micrococcal nuclease and chemical cleavage studies, as well as a novel DNase I analysis that tested small stretches across the intergenic chromatin region for their ability to produce the nucleosome-diagnostic, 10-bp ladder pattern. This organization has been observed in nuclei and *in vivo*, in studies from several laboratories. The promoter regions of other GAL genes, including the regulatory gene GAL80, show a similar chromatin organization. Thus, it may be a general feature of GAL genes.

In the carbon source galactose (the active state of expression), the three promoter nucleosomes A–C appear to be completely removed (disrupted), thus exposing the underlying DNA sequences, including the TATA and start sites, to transcription factors. The HR region remains highly accessible. Recent *in vitro* fluorescence studies (involving the Lohr laboratory) have shown that nucleosome A, which covers the GAL10 TATA, has a lower intrinsic stability and higher levels of inherent DNA dynamics than nucleosomes typically studied. Thus, this nucleosome may be especially susceptible to disruption.

In contrast to the promoter nucleosomes, the GAL1 coding sequence nucleosomes remain present under actively induced conditions. However, they do appear to have undergone alteration compared to their structure in the inactive state. This probably involves conformational change and perhaps a reshuffling of locations, although the precise nature of the alteration remains unclear. Coding sequence and promoter nucleosomes on GAL1–10 show other differences (see below).

The Role of Promoter Chromatin Structure in GAL1–10 Regulation

Factors and Chromosomal Organization

The active (galactose-induced) state

In cells growing in galactose, the transcription activation function of Gal4p is free of Gal80p inhibition and the GAL1–10 genes are transcribed at very high levels. Under these conditions, Gal4p is bound, via its N-terminus, to the UAS_C elements in the

HR region between GAL1 and GAL10 (Figure 1) while activating transcription through its C-terminal activation domain. The UAS_C elements are more than 200 bp (>680 Å in linear DNA distance) from the GAL1 to GAL10 transcription start sites, suggesting that the three-dimensional structure of Gal4p and promoter chromatin architecture, both unknown, may impact the transcription process.

In this active state, the DNA in the TATA and transcription start site regions is freed from nucleosome protection, due to the complete disruption of nucleosomes A–C. This DNA exposure should greatly facilitate the binding of factors to these regions, such as the binding of TBP to the GAL1 and GAL10 TATA elements. TBP cannot bind to DNA that is nucleosome covered.

Inactive states (poised or repressed)

There are two distinct types of inactive states, repressed (in glucose) or poised for expression (in nonrepressing, noninducing carbon sources such as gly–lac). In both types of inactive states, there is no detectable transcription of the GAL1–10 genes. In both, Gal80p is bound to the Gal4p activation domain, inhibiting its activity, and nucleosomes A–C are present on the TATA and transcription start site regions, inhibiting factor access to those DNA sequences.

In the poised state (cells growing in gly–lac), the inactive GAL1–10 genes can be rapidly (within minutes) brought to full, high-level expression by the addition of galactose to the growth medium. In gly/lac, Gal4p is bound to the GAL1–10 UAS_C elements, even though there is no transcription. Moreover, the level of UAS_C protection by Gal4p, and thus the strength of Gal4p–UAS_C binding, appears to be similar to that in galactose-grown cells. Elevated Gal4p levels (GAL4 is most highly expressed in carbon sources such as gly–lac) plus constitutive accessibility of the UAS_C elements in the chromosome structure probably account for the UAS_C occupation by Gal4p, and the rapid inducibility, in these carbon sources. Thus, although inactive, the GAL1–10 genes are poised for the rapid induction of expression.

The gly–lac results show that the DNA binding and transcription activation functions of Gal4p act independently in the cell and respond to different controls: DNA binding to Gal4p levels and transcription activation to Gal80p. In addition, location of the UAS_C elements within a large, nucleosome-free region means that Gal4p does not have to compete with nucleosomes nor depend on the action of nucleosome modification factors to gain access to its target elements. The constitutive accessibility of the UAS_C and the independence of Gal4p DNA binding and activation functions are key features (along with elevated Gal4p levels) that permit the existence of a poised state. Such a state would have been a major advantage to wild yeast, allowing cells growing on poorer carbon sources to efficiently utilize galactose, a relatively good carbon source, even if it is only transiently available.

The presence of glucose imposes an additional negative regulation on the GAL1–10 genes, the absence of Gal4p from the UAS_C. This feature prevents GAL1–10 from being (rapidly) inducible in glucose. The UAS_C elements reside in the same size, highly accessible, nucleosome-free region in glucose- or gly/lac-grown cells and thus should be equally available for Gal4p binding in both carbon sources. The absence of Gal4p from the UAS_C is thought to result, at least in large part, from low Gal4p levels due to decreased expression of the GAL4 gene

in glucose. This regulation is imposed by the global, glucose repression apparatus, a system that helps insure the preferential utilization of glucose. The decrease in GAL4 expression is modest but Gal4p–UAS_G binding should be very sensitive to Gal4p levels due to its highly cooperative nature (multiple UAS_G/two Gal4p per UAS_G).

Regulating GAL1–10 Expression: A Dynamic Interplay of Promoter Nucleosomes and Regulatory Factors

Chromatin structure is now seen as a major facet of eukaryotic gene regulation; studies of GAL1–10 promoter chromatin, beginning in the mid-1980s (in the Lohr laboratory), provided early indications of this important association. Studies since that time, in several laboratories, have provided insights into various aspects of this relationship on GAL1–10. These studies have shown that regulation of GAL1–10 expression involves complex interactions among the gene-specific regulatory factors, general factors, and the promoter nucleosomes A–C. The rigor of these conclusions reflects the ability to couple biochemical and genetic analyses in the study of genes in single-copy number.

In addition to their other functions, the specific regulators Gal4p and Gal80p also play crucial roles in determining nucleosome occupation on the GAL1–10 promoter region. Gal4p mediates the characteristic disruption of the promoter nucleosomes A–C observed in the induced state. As noted above, this provides DNA access for factors such as TBP. This nucleosome disruption has been shown to be a specific and dedicated activity of the Gal4p activation domain and not simply a secondary consequence of the transcription process (by the Majors laboratory). Whether Gal4p acts directly or through other factors is unknown. Other activation-associated activities of Gal4p include the recruitment of cellular complexes such as SAGA, Mediator, probably Swi-Snf, and perhaps RNA polymerase II itself (Figure 1).

In addition to inhibiting Gal4p activation activities in nongalactose carbon sources, the negative regulator Gal80p also mediates the replacement (reposition) of disrupted promoter nucleosomes A–C when conditions are unfavorable (loss of activation signals, low cellular energy levels) for transcription (shown by the Lohr laboratory). This can even occur in cells initially grown in galactose, when they are starved for energy. Energy sensitivity is not unexpected because it links the disrupted state, and thus transcription capability, to cellular energy levels. Whether Gal80p carries out redeposition directly or through other factors is unclear.

Gal80p modulates the levels of GAL1–10 induced expression, keeping them lower than inherently possible. This may explain the surprising observation that expression of this negative regulator is actually enhanced in galactose (5–10-fold); enhancement is Gal4p-dependent and mediated through a UAS_G on the GAL80 promoter. Gal80p is also involved in maintaining promoter nucleosome coverage under inactive (noninduced) conditions; Gal80p removal results in a partial loss of protection in the nucleosome A–C regions, and low levels of GAL1 expression, under these conditions. Both promoter modulation under induced conditions and nucleosome maintenance under noninduced conditions may involve the nucleosome redeposition activity of Gal80p.

The reciprocal processes of nucleosome disruption, mediated by Gal4p, and redeposition, mediated by Gal80p, are dynamic and reversible. Galactose addition can trigger promoter nucleosome disruption in minutes; nucleosome redeposition, during starvation for example, occurs in well under an hour (and perhaps minutes as well). The three promoter nucleosomes, A–C, are always found in the same state, disrupted or intact, and all three show a similar disruption/redeposition response, suggesting that they are affected in unison and by the actions of common, concerted processes.

Gal4p/Gal80p-dependent disruption/redeposition is a unique response of the promoter nucleosomes A–C. The GAL1 coding region nucleosomes do not show such a response (nor do they undergo complete disruption under induced conditions (see above)). That the promoter nucleosomes are specific targets of Gal4p/Gal80p action suggests they have a unique, regulatory type of role as opposed to the coding sequence nucleosomes whose responses are consistent with secondary consequences of the expression process. Gal4p–UAS_G binding in the HR region has no detectable effect on nucleosomes A–C (cf. in gly/lac) and disruption of nucleosomes A–C (in galactose) occurs with no apparent effect on the accessibility of the HR region. Thus, the nucleosome-free HR, the promoter nucleosomes A–C, and the coding sequence nucleosome region seem to behave independently, like small mini-domains.

The Grunstein laboratory has studied, in some detail, the role of nucleosomes and histones in GAL1–10 expression. Nucleosomes have a general repressive effect; their (partial) depletion allows some TATA-driven, Gal4p-independent GAL1 transcription, even in glucose. Repression requires the N-terminal tails of all four histones. The promoter nucleosomes and particular histone components also play specific roles in GAL1–10 expression. The N-terminal tails of histone H4 are needed for full levels of galactose-induced GAL1 expression; this positive role involves the nucleosome B region on the promoter. By contrast, the H3 tails function in a process that modulates induced expression; their removal results in an elevated level of GAL1 transcription in galactose. This effect depends on the UAS_G elements. The removal of H4 N-terminal tails decreases DNA accessibility just upstream of the GAL1 TATA, in the nucleosome B region. Deletion of H3 tails has no effect on the promoter nucleosome regions, consistent with the UAS_G association of the H3 effect.

These H3/H4 effects probably involve acetylation because mutation of the tail acetylation sites produces the same effects as tail removal. One possibility is that these tails are contact sites for nucleosome transactions such as disruption/redeposition. For example, removal of Gal80p and H3 tail removal produce similar elevations in induced expression. Notably, the effects of H3 and H4 tail deletions on coding sequence nucleosomes are similar to one another, so the above specific effects are further examples of unique promoter nucleosome features.

Binding of TBP to the TATA regions on the GAL1–10 promoter is undoubtedly a crucial feature and a critical early step in the transcription process. TATA occupancy on the GAL1–10 promoter can be viewed as a competition between TBP and the promoter region nucleosomes A and B/C (Figure 1); the presence of the latter excludes the former. Active conditions (growth in galactose) produce the disruption of nucleosomes A–C, via a Gal4p-dependent process. The attendant exposure

of the TATA-containing DNA regions favors TBP binding and transcription. Under gene-inactive conditions (growth in non-galactose carbon sources or low cellular energy), nucleosome presence on the A–C regions is favored, mediated via a Gal80p-dependent process, and TBP binding and transcription are disfavored (**Figure 1**). Therefore, TATA availability, and thus transcriptional activity, reflects a nucleosome disruption/redeposition competition mediated by the gene-specific regulators Gal4p and Gal80p. Such a competition can provide a dynamic switch for the control of Gal1–10 transcription. Gal4p and Gal80p may be well suited for such a control function because they probably associate with each other in all carbon sources, albeit in differing manners.

In summary, the major GAL1–10 promoter elements (UAS_G) reside in a constitutively accessible, nucleosome-free region, always available for binding by the major activator Gal4p; Gal4p does not have to compete with nucleosomes to access the UAS_G. Positioned, promoter nucleosomes surround this accessible region; their presence or absence depends on dynamic, gene-specific regulatory factor-mediated processes that control DNA access in these regions and thus TATA and transcription start site availability.

Glossary

Chromatin Generic term used for (1) material in the nucleus that stains strongly with basophilic dyes and (2) the complex of DNA and chromatin that may be extracted from nuclei for *in vitro* study.

Histone Family of highly conserved, small basic proteins that constitute the principal protein components of chromatin.

Histone modification Covalent addition of one or more chemical groups to a specific amino acid in a histone. Modifications include acetylation, methylation, phosphorylation, poly-ADP ribosylation, and ubiquitination (ADP, adenosine diphosphate).

Histone variant (subtype) A histone molecule derived from a different gene and having specific amino acid differences from the canonical histone type.

Nonhistone chromatin proteins Generic term for proteins other than histones that may be bound to chromatin.

Nucleosome The complete repeat unit consisting of a nucleosome core particle and the linker DNA that continues to the next nucleosome core particle, often with histone H1.

Nucleosome core particle The disk-shaped (11 nm diameter, 6 nm high) complex of 146 bp of DNA and octamer of histones H2A, H2B, H3, and H4 that is the fundamental structural unit of chromatin. The X-ray structure of the core particle has been solved.

The term 'chromatin' was coined by cytologists to designate the brightly staining portions of nuclei exposed to basic dyes. Although this terminology is still in effect, in the context of biological chemistry, chromatin usually refers to the complex of DNA and protein that is present in the interphase nucleus, and can be isolated for study *in vitro*. As with all biological systems, the physical organization of chromatin results from the intrinsic biochemical properties of the components as influenced by the composition of the aqueous milieu. As chromatin organization plays a crucial role in many aspects of gene regulation, there is much interest in understanding the basic principles involved. Here, the current status of this challenging task is discussed in terms of the major components of chromatin, their interactions, and the complex, dynamic biopolymer that results.

A crude analysis of isolated chromatin reveals a 1:1 ratio of DNA and histones, small, highly conserved basic proteins. Four species of histone (H2A, H2B, H3, and H4) contribute two copies each to the histone core of the nucleosome, a disk-shaped structure 11 nm in diameter and 6 nm in height, while histone H1 binds to the exterior of the nucleosome. Other proteins bound to DNA in chromatin are collectively known as nonhistone chromatin proteins (NHCPs) and include both structural and enzymatic components. Thus, at the simplest level, the physical organization of chromatin consists of very long linear arrays (one for each chromosome) of nucleosomes arranged in a beads-on-a-string conformation, together with bound NHCPs. This primary structure is variously folded and compacted, and (in the interphase nucleus) occupies a distinct volume or territory with little or no intermixing with other chromosome territories. Prior to cell division, a complex series of events transforms interphase chromatin into the familiar linear metaphase chromosomes. It is clear that the arrays of nucleosomes are exposed to a wide range of local and global factors that influence the degree of chromatin compaction, and the challenge has been to understand the impact of these

factors on the physical organization. There is strong evidence that features of chromatin organization such as compaction level are related to mechanisms of differential gene expression. Further, some aspects of chromatin organization are important in epigenetic inheritance, whereby properties such as differential gene silencing or activation are inherited not as differences in DNA sequence but as specific chromatin structures and their components.

Global factors that influence the physical organization of chromatin include the ionic milieu of the nucleus, especially the concentrations of monovalent and divalent cations, and polycations such as polyamines. The combination of charge shielding and charge neutralization that results from exposure of chromatin to cations *in vitro* results in stronger intra-chromatin interactions (as the self-repulsive properties of DNA are negated) and greater compaction. Indeed, at the concentration of cations thought to be present in the living nucleus, chromatin *in vitro* tends to aggregate and essentially precipitate. Modulating the effects of cations are local variations in nucleosomes (histone variants and histone modifications), DNA modifications (chiefly cytosine methylation), and bound NHCPs (often related to histone modifications). Thus, the chromatin template has the potential to assume a continuum of compaction levels, and it is in this context that its physical organization has to be viewed. In this article, the principal variables that can influence the structure and function of a given portion of the genome are outlined, after which the question of physical organization is discussed.

Variables That May Influence Chromatin Physical Organization

Posttranslational Modifications of Core Histones

The presence of a large variety of core histone modifications has been known for many years, but its role in chromatin

was very poorly understood. Recently, however, evidence has grown that the pattern of histone modifications on an individual nucleosome or array of nucleosomes may encode information that is essential in determining a variety of functional states. Many modifications occur on the N-termini of the core histones which project from the nucleosome and are unstructured in the sense that they are not detected in nucleosome crystals by X-ray analysis. Some, such as acetylation and methylation of lysine residues, result in the net loss of a positive charge and may result in a change in chromatin conformation *per se*. However, it is clear that the functional implications of histone modification result from far more complex effects than modulations in compaction resulting from alterations in charge balance.

For example, H4 acetylation can occur at one or more of four lysines in the N-terminus, and these modifications alone, and in combination, carry important functional signals. The net acetylation pattern is the result of the balance between histone acetylase (HAT) enzymes and histone deacetylase (HDAC) enzymes. Both HAT and HDAC enzymes tend to occur in large complexes that may contain proteins that serve to target the enzymatic activity to the appropriate gene(s). Specific acetylation patterns also occur on newly synthesized chromatin and are erased after deposition as nucleosomes move close to the replication fork.

Another key set of histone modifications involves the methylation of lysines on histone H3. Here, another level of complexity arises because the methyl transferases may deposit one, two, or three methyl groups, and the number of methyl groups provides another signal. Certain methylation patterns are important in providing binding sites for a group of NHCPs known as 'heterochromatin protein 1 (HP1)'. HP1 tends to accumulate on transcriptionally silent chromatin and appears to be involved in the downregulation of genes.

Variants of Core Histones

Typically, higher organisms have several genes for each of the core histones, some of which may be identical in sequence, while others vary in amino acid sequence. The majority of core histone genes is transcribed only during DNA replication and is incorporated into nucleosomes in the wake of the replication fork. Others are synthesized constitutively and incorporated into nucleosomes only after the relatively rare event of displacement of a complete histone octamer. An interesting example is provided by the replication coupled 'bulk' H3 and the H3.3 variant which can be deposited in both replication-coupled and replication-independent pathways, and which differ at only four amino acid positions. Single amino acid changes of H3 toward H3.3 allow replication-independent deposition. H3.3 accumulates modifications that favor transcription, while H3 accumulates lysine methylations, a mark of inactive chromatin. The ratio of H3.3 to H3 increases steadily in nondividing long-lived cells (such as neurons) and, through this mechanism, may become the major H3 variant. Another H3 variant which is highly conserved evolutionarily occurs only in centromeric chromatin and plays a crucial role in cell division.

Histone H1

Histone H1, also known as 'linker histone', plays a dominant role in establishing the compaction state of an array of nucleosomes as well as influencing the conformation. H1 has three domains: a central globular domain that binds near the entry/exit site of linker DNA on the nucleosome, and extended N- and C-terminus. The C-terminus is particularly rich in the basic amino acids lysine and arginine and, thus, has a strong propensity to bind DNA. H1 binding protects an extra 20 bp of nucleosomal DNA from nuclease digestion, a protection conferred by the globular region alone. There is a general correlation between the amount of H1 in chromatin and its ability to be transcribed, and most models of transcriptional regulation call for the temporary displacement of H1. The silencing effect of H1 could be due to the sealing of two turns of nucleosomal DNA, thus preventing the unwrapping needed for RNA polymerase, or due to the H1-induced physical compaction of arrays of nucleosomes, or most likely to a combination of both.

Like the core histones, there are several variants of H1 in most higher organisms, but little is known about their individual properties. Genetic manipulations of mice that knock out one or two variants produce no observable phenotype, and the remaining variants are upregulated to compensate for the loss. The loss of additional variants leads to a depletion in total H1 and eventually to embryonic lethality, although embryonic stem cells may be rescued from H1-depleted nonviable embryos and grown in culture. H1-depleted nuclei do not exhibit a general depression of transcription, as predicted by the simple model that H1 loss should create open and permissive chromatin.

Nonhistone Chromatin Proteins

A two-dimensional (2D) gel of the proteins bound to the chromatin of an active nucleus reveals hundreds of spots, and it is clear that there are many other proteins present in low abundance that are revealed only after staining with specific antibodies. To date, relatively few have been studied in detail, and most of these are either abundant in the nucleus or came to researchers' attention through functional studies of specific genes or classes of genes. Most NHCPs can be eluted from chromatin by treatment with 0.3–0.4 M monovalent ions (usually NaCl), in contrast to H1 which requires 0.5–0.6 M NaCl and the core histones which elute between 0.8 and 2.0 M salt. There is some evidence that the few proteins that remain bound in 2.0 M salt contribute to a nuclear skeleton (karyoskeleton and nuclear matrix), which provides structural integrity to the nucleus and has an important dynamic role in its spatial organization as well as replication and transcription. However, despite much effort, it has not been possible to reveal an *in vivo* karyoskeleton analogous to the cytoskeleton, and the possibility that the residual proteins in salt-extracted (and usually DNase-treated) nuclei represent an aggregation phenomenon has not been excluded. The finding that the most abundant nuclear matrix proteins are associated with the peripheral nuclear lamina or are part of the RNA transcript processing machinery has reinforced these concerns.

Table 1 Hierarchical classification scheme for chromatin physical organization

<i>Level of chromatin physical organization</i>	<i>Examples of global features</i>	<i>Examples of local features</i>
Primary – the linear arrangement of nucleosomes on DNA	The nucleosome repeat length	Preferred locations of nucleosomes and features such as DNase hypersensitive sites on a specific DNA sequence.
Secondary – structures formed by interactions of nucleosomes	The 30-nm chromatin fiber	3D architecture of nucleosomes and regulatory proteins on a specific DNA sequence.
Tertiary – structures formed by interactions between secondary structures	Thicker fibers seen in nuclei and postulated to be composed of 30-nm fibers	Long-distance contacts possibly involving locus control regions, enhancers and promoters, or looped chromatin domains.
Quaternary and above – structures formed by interactions between tertiary structures, etc.	No unambiguous examples – see text	Interphase chromosome territories; metaphase chromosomes

The ubiquitous and abundant (typically 1 per 10–15 nucleosomes) high-mobility group (HMG) proteins elute from nuclei in 0.3–0.4 M salt and were originally grouped together on the basis of their solubility properties and rapid mobility in gels. Members of the HMG-B group share the HMG-box functional domain, which contains three α -helices and, when bound to double-stranded DNA, induces a bend of 90°. By contrast, the HMG-N family of proteins bind to nucleosomes via a nucleosome-binding domain (NBD), resulting in a change of conformation and the stimulation of transcription and replication. Finally, the HMG-A family members contain three A-T hook motifs that bind preferentially to the minor groove of DNA rich in AT sequences. HMG-A proteins appear to participate in a wide range of chromatin-based processes and are often upregulated in cancerous cells. The lack of sequence specificity of all the HMG proteins suggests that they are targeted to the appropriate sites by interactions with other nuclear proteins, and evidence is accumulating for many such interactions.

The HP1 family of NHCPs, known to play a role in epigenetic inheritance, is also conserved across a wide range of eukaryotes, with three isoforms, α , β , and γ , found in mammalian nuclei. HP1 (as well as several other important NHCPs) molecules share a chromo domain which binds not to DNA but to the methylated form of lysine 9 on histone H3. HP1 also interacts with numerous other proteins, including an enzyme that methylates H3. This illustrates the complex interactions and feedback loops that are probably widespread in the nucleus.

The protein families discussed above are certainly only a small subset of the repertoire of NHCPs, but perhaps representative of the different modes of action, which range from modifying chromatin architecture to acting as targets for other proteins. Most NHCPs are not stably bound to chromatin, but are remarkably mobile within the nucleus.

Levels of Physical Organization

The large number of variables in chromatin composition has the potential to influence its global and local physical organization, especially the degree of compaction, and the related level of transcriptional competence (higher compaction correlates with reduced transcription). A useful approach is to consider chromatin compaction in terms of hierarchical levels of folding, using a nomenclature based on that devised for

proteins (Table 1). For chromatin, it is necessary to distinguish between local structures that may be confined to specific genes, portions of genes, or groups of genes and global structures that are nucleus wide.

Global Primary Structures – the Nucleosome Repeat Length

While the length of DNA incorporated into the nucleosome is fixed at 146 bp, the length of linker DNA between nucleosomes is variable. At the level of the whole nucleus, each cell type in an organism has a characteristic average nucleosome repeat length (NRL), most mammalian cells having NRLs between 175 and 195 bp. The longest NRLs, measured to date, ~240 bp, are in echinoderm sperm (which have unusual core and H1 histones) and the shortest, ~165 bp, are derived from yeast (*Saccharomyces cerevisiae*), which lack a typical histone H1. The number of H1 molecules per nucleosome varies among cell types; there is a straight-line relationship between H1 abundance and NRL, cells with higher H1/nucleosome ratios having longer NRL values. Such a relationship tends to maintain a fixed net charge within nuclei.

Local Primary Structures

For a given cell type, local NRLs vary about the global mean, with spacings between individual nucleosomes somewhat influenced by the underlying DNA sequence. In addition, there are many instances where nucleosomes on particular genes and gene-regulatory sequences may be positioned with base-pair precision, and thus the local NRL may differ from the global NRL. This local positioning often contributes to transcriptional regulation. For example, a nucleosome positioned on a promoter sequence may block the binding of proteins and protein complexes that are required for transcription initiation. Relieving such a transcriptional block may be achieved by shifting nucleosomes, a process catalyzed in an adenosine triphosphate (ATP)-dependent reaction by several families of large, multi-component nucleosome remodeling complexes. Other cases are known where a specific DNA sequence is normally nucleosome free. These sites, which are most common in gene-regulatory sequences and are probably occupied by NHCPs *in vivo*, may be detected by their hypersensitivity to endonucleases.

Specialized DNA sequences may have a characteristic NRL that differs from the global value. For example, the long stretches of gene-free chromatin at the ends (telomeres) of chromosomes, which consist of tandem repeats of TTAGGG, typically have a shorter NRL than bulk chromatin.

Local primary structures may also be influenced by cytosine methylation of CpG dinucleotides, followed by binding of methylated DNA-binding proteins (MBDs). Some MBDs have binding sites for HDAC complexes, leading to local histone deacetylation and hence transcriptional silencing, and there is evidence that MBDs may promote chromatin compaction.

Global Secondary Structures – the 30-nm Chromatin Fiber

If chromatin is isolated from nuclei and observed by electron or atomic force microscopy, it is seen to have a conformation highly dependent on the ionic strength of the medium – at low ionic strength (5–25 mM Na^+), the linear array of nucleosomes is clearly seen, while at higher ionic strengths, increasing compaction occurs, leading to the formation of an irregular fiber ~ 30 nm in diameter. This reversible transformation, which is dependent on H1, can also be monitored by changes in physical properties such as sedimentation velocity. Much research effort has been expended on determining the physical organization of the 30-nm fiber, and several different models have been proposed. The most widely discussed are solenoidal structures in which the linker DNA continues the superhelix established in the nucleosome, creating a stack of coins which subsequently coils into a 30-nm diameter fiber, and zigzag structures in which the linker DNA remains more or less straight and compaction results from the accordion-like compression of the zigzag. Among recent results supporting a zigzag arrangement are computer models derived from force-extension curves of individual chromatin fibers (Figure 1), which bear a striking similarity to native chromatin fibers imaged in the hydrated form (Figure 2). The physical irregularity of native chromatin fibers, which probably results largely from the local variations in NRL, has contributed to the ongoing controversy. The ability to reconstitute artificial chromatin with regularly spaced nucleosomes has provided important insights into the structure of the 30-nm fiber. Using this

Figure 1 Computer models of chromatin secondary structure at different levels of extension (F_{ext}) based on force-extension data derived from pulling single chromatin fibers. Nucleosome core particles are represented by red spheres and linker DNA by green rods. Modified from Katritch V, Bustamante C, and Olson WK (2000) Pulling a single chromatin fiber: Computer simulations of direct physical manipulations. *Journal of Molecular Biology* 295: 29–40.

approach, it has been possible to crystallize and solve the X-ray structure of defined tetra-nucleosomes that lacked H1 but were compacted using high levels of divalent cations. These clearly adopt a zigzag conformation with straight linker DNA segments, such that nucleosome 1 associates with nucleosome 3 and nucleosome 2 with nucleosome 4. Other approaches using sophisticated computer modeling that incorporate thermodynamic and charge effects also suggest that long polynucleosomes adopt a primarily zigzag conformation. However, some models call for a subset of nucleosomes with bent linker as would be predicted for a solenoidal architecture. This type of heteromorphic organization has been observed by direct examination of defined polynucleosomes. *In vivo*, local variations in NRL, histone modifications, histone variants, and occupancy by NHCPs are likely to create a highly irregular chromatin fiber organization.

Local Secondary Structures

There is much evidence that local chromatin secondary structures play a large role in chromatin function by promoting or repressing transcription, but little is known of the precise physical organization of these local structures. In some instances, it has been demonstrated that a stretch of chromatin may accumulate many copies of NHCP that acts as a transcriptional silencer (e.g., HP1), but the difficulty of isolating single-gene chromatin for observation precludes rapid progress.

Tertiary and Higher-Level Features

Although it is often assumed that native chromatin exists as a series of hierarchical structures above the 30-nm chromatin fiber (and such illustrations are common in textbooks), there is very little solid supporting data. Methods used to examine isolated 30-nm fibers fail to reveal tertiary or higher levels of folding as the ionic strength is increased toward the physiological level. Rather, chromatin tends to aggregate. Examination of thin sections of nuclei in the electron microscope reveals many different fiber diameters ranging up to 240 nm, with no clear

Figure 2 Chromatin fiber observed in the frozen hydrated state in 20-mM NaCl. Many of the nucleosomes are viewed edge-on and appear as dark ovals. Arrowheads point to two nucleosomes showing the circular enface profile. The zigzag secondary structure bears a strong resemblance to the model in Figure 1. Scale = 30 nm. From Bednar J, Horowitz RA, Grigoryev SA, et al. (1998) Nucleosomes, linker DNA, and linker histone form a unique structural motif that directs the higher-order folding and compaction of chromatin. *Proceedings of the National Academy of Sciences of the United States of America* 95: 14173–14178.

hierarchical arrangement. Indeed, only under rather specialized conditions and with inactive nuclei can 30-nm fibers be routinely observed in sections. Whether this lack of order *in situ* is due to problems of adequate structural preservation, or simply due to a very unstructured and dynamic native organization remains to be seen.

Chromatin Organization *In Vivo*

Most of the work on chromatin physical organization discussed above has been conducted *in vitro* using chromatin isolated from nuclei or reconstituted from the individual components. However, it is important to verify that structures studied *in vitro* actually exist *in vivo*. For chromatin, such verification has been difficult. For example, sections of nuclei observed by EM mostly show dense masses of chromatin with no signs of individual 30-nm chromatin fibers. The few types of cells where 30-nm fibers can be seen in thin sections tend to be transcriptionally inert and have specialized H1-type histones and long NRLs (e.g., echinoderm sperm and avian erythrocytes). It has been suggested that the absence of a fiber structure even in frozen hydrated sections of unfixed nuclei and chromosomes is due to a tendency for nucleosomes in adjacent fibers to interdigitate, with the result that the chromatin behaves like a molten polymer. The high density of chromatin *in vivo* will favor this type of behavior. When removed from the nucleus, segments of chromatin are greatly diluted from their *in vivo* state, revealing the underlying 30-nm fiber organization.

Although *in vivo* studies have failed to shed much light on chromatin secondary structures, they have provided important insights into higher levels of organization through a number of related techniques collectively known as ‘chromatin conformation capture’ or 3C. The underlying strategy is to cross-link living nuclei with formaldehyde so as to capture segments of chromatin in close contact. Chromatin is then isolated and cleaved into small fragments, after which a desired subset containing the feature of interest, such as a histone variant, histone modification, and specific NHCP, is purified typically via immunoprecipitation. Finally, the cross-links are reversed, and the associated DNA sequences identified. To date, 3C and variants of the technique have revealed important features of chromatin architecture, including the suggestion that chromatin adopts a fractal organization *in vivo*. 3C methods are rapidly evolving, and as resolution increases through the use of massively parallel high-throughput screening, rapid progress can be anticipated.

Chromatin Dynamics

Recent work has revealed that living nuclei are remarkably dynamic. While the nucleosome core histones are long-lived

and stably incorporated, histone H1 binds to chromatin with a half-life of a few minutes, and most NHCPs have half-lives of a few seconds. Modeling of chromatin fibers based on thermodynamic principles indicates a constant fluctuation in local compaction. Also, individual clusters of genes may change dramatically in compaction state and even location in the nucleus when transcription is stimulated. These observations reinforce the concept of the living nucleus as a highly dynamic entity, both in terms of genetic activity and physical organization.

Glossary

Chromatin The highly dynamic complex of DNA, histones, and nonhistone proteins from which the eukaryotic chromosome is built; it is generally used in reference to the interphase form and can refer to the sum of all chromosomes.

Chromosome Structural unit of the genetic material in eukaryotes. It consists of one double-stranded DNA molecule, packaged as interphase chromatin or a metaphase chromosome. Eukaryotes have

from 1 to over 200 chromosomes, depending on the species.

Nucleosome Fundamental repeating subunit of the chromatin fiber, consisting of a core histone octamer (made up of two molecules each of H2A, H2B, H3, and H4) with DNA wrapped around the surface in nearly two left-handed turns, connected by linker DNA associated with one molecule of linker histone (usually H1) to the next subunit. Each repeating unit (core plus linker) packages about 200 bp of DNA.

The Structure of Chromatin

The nucleotide sequence of DNA represents the primary level of chromosome organization. When a DNA molecule is packaged into chromatin, the latter does not behave as a uniform fiber. The chromosome conformation is affected by regulatory and structural features. These sequence elements include promoter proximal elements that control the activity of individual genes, locus control regions that impact a cluster of genes, and boundary elements that potentially regulate the activity of large (10–100 kb) chromosomal domains. In addition to the unique sequences that code for genes, eukaryotic genomes include a high percentage of repetitious DNA, both tandem arrays of short-repeating motifs (often identified as satellite DNA because of its different density) and dispersed relics of transposable elements, retroviruses, and the like. Some of the repetitious DNA is utilized in the generation of special chromosome structures such as the centromere, the site of microtubule attachment during mitosis, and the telomeres, structures that protect the ends of the DNA molecules.

The discovery of nucleosomes, repeating subunits based on DNA folding around an octamer of histones, provided a molecular description of the fundamental unit of chromatin folding and accounted for the first six- to sevenfold linear compaction of the DNA. The octamer, containing two molecules each of the core histones H2A, H2B, H3, and H4 (a tetramer of $[H3+H4]_2$ plus two dimers of $[H2A+H2B]$) with 147 bp of DNA wrapped around it in 1 2/3 left-handed turns, makes up the core particle. The high-resolution 2.8-Å structure reveals the details of histone organization within the nucleosome (Figure 1). The C-terminal two-thirds of the histone molecules, folded in a hand-shake motif, form the core of the nucleosome, while their amino-terminal tails extend outward and are potentially involved in further interactions with DNA, with other proteins, and between adjacent nucleosomes. Typically, 170 bp of DNA follows a bent path round the histone core, held strongly by electrostatic bonds between the basic amino acids of the histones and the phosphates of the DNA. The segments of DNA that link adjacent nucleosome core particles (linker DNA) are bound by linker

histones (H1 and its variants) or HMG proteins. These proteins contribute to the further folding of the chromatin fiber, playing a role in the condensation of the 10-nm fiber to form a 30-nm fiber (Figure 2).

The arrangement of nucleosomes within the 30-nm fiber is still very controversial. A widely utilized model, derived primarily from physical measurements and diffraction studies, is based on a solenoid, in which the nucleosomal fiber is wound in a regular helix, with about six nucleosomes per turn. The linker histones face inward and help to stabilize the solenoid. However, advanced single-molecule methods, using microscopy and spectroscopy to study single chromatin fibres, suggest that the chromatin fiber is an irregular helix, with a fluctuating zigzag secondary structure. Comparative studies suggest that the linker DNA with the associated linker histone affects the DNA topology and the higher-order folding and compaction of chromatin along the 30-nm fiber axis (Figure 2(b)).

The 30-nm fiber is thought to be the basic form of much of the chromatin during interphase. However, a subfraction of the chromatin remains condensed, and darkly staining (heteropycnotic), as the cell returns from metaphase to interphase. This condensed fraction is referred to as 'heterochromatin', while the more diffuse material is labeled 'euchromatin'.

Heterochromatic domains contain a high proportion of repetitious DNA sequences (satellite DNA, retrotransposons, and other transposable element relics), have a low gene density, are replicated late in S phase, and show little or no meiotic recombination. These domains are typically associated with methylation of histone H3 at lysine 9, with concomitant association of heterochromatin-specific proteins such as HP1. Genes normally resident in euchromatin become inactive when placed in or near a heterochromatic environment by rearrangement or transposition. The factors that define specific chromosomal domains as preferred sites of heterochromatin assembly are not well understood, but it appears likely that heterochromatin formation is linked to the presence of repeated DNA sequences. Heterochromatic regions show a more regular nucleosome array (more even spacing) than

euchromatic regions, as well as a loss of nucleosome-free regulatory regions; however, the nature of the difference in higher-order packaging between heterochromatin and euchromatin remains unknown.

Chromatin structure is intimately involved in the regulation of chromosome activities: replication, transcription, and repair. The packaging of a DNA protein-binding motif with histones in a nucleosome often renders that signal invisible to the protein. For example, packaging of a TATA box sequence into a nucleosome blocks initiation of transcription; assembly of a restriction site

into a nucleosome blocks cleavage by that restriction enzyme. Thus, it is no surprise that chromatin needs to undergo significant structural change, or remodeling, to enable the cellular machines that perform various functions to gain access to their template, the double-helical DNA. The challenge to understand chromatin structure and dynamics, and to link chromatin structure to function, is enormous. Current research has highlighted the role of posttranslational modifications of both the histones and the DNA in marking different structural states and providing appropriate signals to the cellular machines.

The core histone proteins are highly conserved. In the most extreme example, there are only two amino acid changes between the sequences of histone H4 from plants and animals. While the globular carboxy-terminal domains make up the nucleosome core, the flexible amino-terminal tails protrude outward from the core structure. These basic tails function as acceptors for a variety of posttranslational modifications, including acetylation, methylation, and ubiquitination of lysine (K) residues, phosphorylation of serine (S) and threonine (T) residues, and methylation of arginine (R) residues. Several studies have shown that histone modifications can be cooperative or conflicting, one modification facilitating or blocking another. The combination of histone modifications present contributes to the chromatin status of small and large regions of the genome and mediates its functional activity. In particular, histone acetylation is associated with gene expression, while deacetylation, with methylation of histone H3 on lysines 9 and/or 27, is associated with silencing. These patterns can be altered by multiple extracellular and intracellular stimuli that signal to the nucleus. In fact, recent studies have shown that many proteins characterized as activators or silencers of transcription work by causing or facilitating a change in the modification state of the histones at a given locus. Thus, chromatin itself has been proposed to serve as a signalling platform and to function as a genomic integrator of various signaling pathways. Covalent modifications of histone tails are believed to act in concert to establish the 'histone code' essential for assembly of the desired chromatin state.

In addition to the proteins that package DNA, there are also sets of nonstructural proteins that interact with specific DNA sequences to control gene expression, interacting with promoters, enhancers, locus control regions, etc. While some such proteins can recognize DNA sequences in a nucleosome, many cannot. Both targeted alterations in histone modification and the remodeling of nucleosomes are often required to allow these latter proteins to function. The order of the required operations for activation of transcription varies at different loci.

Other nonhistone proteins contribute to structural elements such as insulators and/or boundary complexes. Insulators define a region of regulatory activity by managing promoter interactions with proximal and distant enhancers; while boundaries (or barriers) limit the spread of heterochromatin into a euchromatic domain. The arrangement of these genomic elements contributes to the functional and structural state of a locus and region. Unfortunately, it has not yet been possible to relate boundary elements, defined by their functional role described above, with the structural elements that anchor chromosomal loops, as seen by electron microscopy, or with the protein scaffold that constrains DNA in supercoiled domains of 10–100 kb. A better understanding of this level of organization will be essential to develop a detailed model of how chromosomes function.

The Role of Spatial Organization of the Genome in the Nucleus

The next level of chromosome organization must take into account the three-dimensional (3D) arrangement of the chromosomes within the cell nucleus. Approaches to microscopy

that allow us to examine the nucleus in 3D have shown that individual chromosomes occupy defined subdomains within the interphase nucleus. This organization involves the interaction of different factors bound to specific sites in the chromosomes with regions of the nuclear envelope and the protein-facilitated juxtaposition of chromosome sites to form stable connections between distant sequences, with intervening loops of the chromatin fiber. There is increasing evidence that both actin and myosin, found inside the nucleus, might have an impact on its internal structure. Noncoding RNAs have also been shown to affect higher-order chromatin organization. Analysis of the spatial distribution of chromatin within the nuclei of individual mammalian cells has revealed distinct variations between cells; these findings may help to explain the epigenetic diversity among genetically identical cells. Unfortunately, our understanding of this higher-level packaging is very meagre compared to our knowledge of the primary levels of organization. Nonetheless, such packaging can be thought of as the culmination of the hierarchy of chromatin structures that functionally connect the linear genomic sequence to the mechanisms for information processing inside the cell nucleus.

The Mitotic Chromosome

Substantial differences in the organization of chromosomes occur during mitosis. The most obvious difference is that the chromosome structure is more compact and the shape much better defined than in interphase chromosomes. This more stable structure has offered some advantages for examining the organization and packaging of the single DNA molecule of a chromatid. Several biochemical and structural studies have argued for the partitioning of the genome into a series of defined units (domains) containing 10–100 kb of DNA. Early EM studies suggested the presence of a chromosome scaffold from which loops of chromatin radiate. The scaffold might be considered as either an axial core, most likely made up of DNA and/or protein, or a loose network of DNA/protein complexes whose regulated assembly controls the higher-order structure of the chromosome. In general, scaffold models presume interactions between specific protein factors and *cis*-acting DNA sequences (SARs, or scaffold attachment regions) that determine the limits of the domains. In most models, two neighboring elements, separated by up to 100 kb of DNA, bind to the scaffold (or to each other) forming a loop. Experimentally, a group of very AT-rich sequences has been identified as potential SARs, based on the association of these sequences with the protein scaffold remaining after histones have been extracted from chromosomes. Using fluorescence *in situ* hybridization (FISH), SARs were visualized as a long queue running the length of the chromosome that alternately followed a fairly linear or tightly coiled path. These images were highly variable. Helically folded mitotic chromosomes have been visualized under certain conditions, suggesting that the highest order of folding is a helical winding of the chromosome arm.

However, *cis*-acting elements affecting chromosome architecture have not been identified by genetic criteria, nor have the proposed SARs (identified by biochemical assay) been mapped successfully in relation to cytological preparations. Recently, biophysical approaches for quantifying the elastic

properties of mitotic chromosomes have provided important insights into their structure. The mechanical integrity of mitotic chromosomes appears to be maintained by links between chromatin fibers, not by a proteinaceous axial core. Isolation of whole chromosomes and reconstitution of mitotic chromosomes have identified topoisomerase IIa, a five-subunit complex termed condensin, chromokinesin, and the chromatin remodeling ATPase ISWI as major constituents. All presumably contribute to the change from the interphase form to the condensed mitotic chromosome. ATPases are very abundant in mitotic chromosome fractions. Probably, these enzymes provide the energy for the aforementioned complexes to induce the local and global conformational changes in chromosomes required to support condensation, and microtubule-dependent movement of assembled chromosomes to opposite poles prior to cell division.

The centromere, observed in all higher eukaryote chromosomes, is a well-known landmark. It takes the form of a distinct primary constriction where the sister chromatids are held together until separated. The constricted region comprises a differentiated chromatin structure onto which microtubules bind to provide proper chromosome movements during the processes of mitosis and meiosis. The centromere in higher eukaryotes is generally made up of massive regions of repetitive sequences. Many observations suggest that there is no specific DNA sequence that is required for centromere formation, strongly implicating an epigenetic mechanism. Five mammalian CENP proteins (CENTromere Proteins) – CENP-A, CENP-B, CENP-C, CENP-G, and CENP-H – are unique and essential to the centromere. Three of these proteins – CENP-A, CENP-B, and CENP-C – have demonstrated DNA-binding activity and are potential candidates for marking the site. CENP-A is a histone H3-like protein that is conserved in mammals and other organisms; it is present only in the nucleosomes of active centromeric regions, where its presence triggers kinetochore formation. A mechanism for initiating centromere formation is not identified at present. Most of the chromatin properties of centromeres are not unique. For example, hypoacetylation of histones, a high level of DNA methylation and late replication, are also characteristic features of noncentromeric heterochromatin. The most attractive candidate for the centromeric mark is CENP-A, but the mechanism for incorporation of CENP-A into only one site per chromosome remains a puzzle.

The ends of eukaryotic chromosomes are organized into telomeres, nucleoprotein structures essential for maintaining the integrity of the genome, the so-called ‘guardians of the chromosome’. Telomeric DNA in the majority of eukaryotes is made up of tandem repeats of short guanine-rich sequences. In some cases (e.g., in *Drosophila*), a subset of transposable elements is maintained at the chromosome ends and guanine-rich repeats are not observed. The telomeres show a very special pattern of chromatin fiber organization, distinct from the rest of the genome. The G-rich sequences can form a quadruple helix. *In vivo*, telomeres are not necessarily linear, but can form looped foldback structures, stabilized by protein components. Many of the key proteins in the telomere have

been identified, although their functions are still incompletely understood. Interestingly, telomeres are not transcriptionally silent. Noncoding RNAs are being produced; it is very likely they are involved in functional and structural regulation of telomeres.

Summary

A chromosome, then, can be considered to be a single double helical DNA molecule, running from one telomere through the centromere to the other telomere. Multiple origins of replication, and many genes, are typically found distributed along the length of the DNA molecule. The DNA is packaged first in a nucleosome array, subsequently in a 30-nm fiber, and finally in higher-order structures. This packaging contributes to gene regulation both at the level of individual genes and at the level of large domains.

Coenzyme A

M D Lane, Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Coenzyme A small molecule (molecular weight usually ≤ 1000) that participates chemically in a reaction catalyzed by an enzyme and upon which the reaction depends.

Electrophile A compound with an electron-deficient atom that can accept an electron pair from a nucleophilic compound with an electron-rich atom.

Nucleophile A compound with an electron-rich atom having an unshared electron pair that can be contributed to an electron-poor atom of an electrophilic compound.

Thioester The condensation product of a carboxylic acid and a thiol ($-\text{SH}$) group formed by removal of a water molecule, for example, $\text{R}-\text{CO}_2\text{H} + \text{Co}-\text{SH} \rightarrow \text{H}_2\text{O} + \text{R}-\text{CO}-\text{S}-\text{CoA}$.

Background and Discovery

Coenzyme A (CoA) was discovered by Fritz Lipmann and his colleagues in the early 1950s. The coenzyme was first isolated from large quantities of pig liver extract as the factor required for the acetylation of sulfanilamide, the assay system used to track CoA during its purification. The discovery of CoA and the characterization and determination of its structure (Figure 1) led Lipmann being awarded the 1953 Nobel prize in physiology or medicine. Lipmann's findings opened the door for the discovery of innumerable roles of CoA, most notably the discovery by Feodor Lynen that active acetate was acetyl-CoA, a key intermediate in the metabolism of carbon compounds by all organisms. In 1964, Lynen was awarded the Nobel prize in physiology or medicine for his discovery of acetyl-CoA and many of the metabolic systems that CoA functions. We now know that CoA plays a key role in carbohydrate, lipid, and amino acid metabolism.

Enzymatic Functions of CoA and 4'-Phosphopantetheine

Chemical Mechanisms of Action

CoA occurs in cells either as free CoA or in the form of its acyl-S-CoA thioester or as 4'-phosphopantetheine (4'-PP), which is part of a multifunctional enzyme. The sulfhydryl ($-\text{SH}$) group of the coenzyme is the functional site that endows it with its unique chemical/enzymatic properties. In all of the reactions in which it participates, CoA serves to activate carboxyl groups ($\text{R}-\text{CO}-\text{OH}$) in the form of an acyl-CoA thioester derivative ($\text{R}-\text{CO}-\text{S}-\text{CoA}$). In this form the acyl group has favorable energetic and mechanistic properties. Energetically, CoA thioesters have high transfer potential (i.e., a high negative free energy change associated with breaking the C-S bond of the thioester) that facilitates driving the acyl transfer reaction in which it participates toward completion. Mechanistically, the chemistry of CoA thioesters facilitates reactions either at the carbonyl carbon ($-\text{CH}_2-\text{*CO}-\text{S}-\text{CoA}$) or the adjacent α -carbon atom ($-\text{*CH}_2-\text{CO}-\text{S}-\text{CoA}$).

Activation of the carbonyl- and α -carbon atoms in acyl-CoA thioesters

All enzymatic reactions of CoA thioesters in metabolism involve activation either of the carbonyl-carbon or the adjacent-carbon atom for facile chemical reaction. Mechanistically, the $-\text{CO}$ -carbon (i.e., $\text{R}-\text{CH}_2-\text{CO}-\text{S}-\text{CoA}$) of the acyl group reacts with a nucleophile (R^- ; see Figure 2, reaction 1) or the adjacent alpha carbon (i.e., $\text{R}-\text{*CH}_2-\text{CO}-\text{S}-\text{CoA}$) reacts with an electrophile (R^+ ; see Figure 2, reaction 2) to produce a new carbon-carbon bond. These reaction types are illustrated in the figure.

CoA as Donor of 4'-PP for Fatty Acid Synthase

Fatty acid synthase (FAS) is a large multifunctional enzyme that catalyzes all steps in fatty acid synthesis, catalysis being facilitated by a covalently linked 4'-PP prosthetic group. The 4'-PP group, which is derived from CoA (Figure 1), is enzymatically transferred to the FAS apoenzyme where it becomes covalently linked to the enzyme. The 4'-PP prosthetic group acts as a long sidearm to which intermediates of the pathway are covalently linked. The 4'-PP sidearm allows translocation of the growing fatty acyl chain intermediate from one catalytic site on FAS complex to the next in the cyclic sequence, which leads to formation of a long-chain fatty acid.

Enzymatic Synthesis of Acyl-S-CoA Derivatives from Free Carboxylic Acids and CoA-SH

The enzymatic reactions by which acyl-S-CoA derivative is synthesized from carboxylic acids, such as free fatty acids, occur through a common mechanism (Figure 3).

The reaction illustrated uses fatty acid as example; however, it should be noted that virtually all acyl-CoAs are formed from their cognate carboxylic acids by the same mechanism. The enzymes that catalyze these reactions are referred to as 'acyl-CoA synthetases'. In the initial step (Figure 3, reaction 1), the fatty acid attacks the (innermost) phosphate of ATP-releasing pyrophosphate (PP_i) forming an enzyme-bound acyl-AMP intermediate. In the second step (Figure 3, reaction 2), CoA-SH

Figure 1 Structure of CoA.

Figure 2 Mechanisms of activation of the acyl carbonyl- and α -carbon atoms in CoA thioesters.

Figure 3 Enzymatic synthesis of acyl-S-CoAs.

attacks the acyl-CO-carbon of the intermediate producing an acyl-S-CoA product and AMP.

Metabolic Roles/Functions

CoA and its derivatives function in a wide variety of metabolic pathways, including the tricarboxylic cycle, fatty acid oxidation, ketogenesis, fatty acid biosynthesis, sterol synthesis, complex lipid synthesis, amino acid metabolism, and porphyrin synthesis. (Since most of these are covered elsewhere in this encyclopedia, they are not dealt with in this article.) As FAS

system is unique, in that it makes use of only a fragment of the CoA molecule, 4'-PP, a brief discussion of FAS is warranted.

Fatty Acid Synthase

Fatty acid synthesis in animals is catalyzed by a single large (molecular weight, 5×10^5 , a dimer consisting of two identical $\sim 2.5 \times 10^5$ subunits) multifunctional enzyme. All eight steps and thus all eight catalytic centers that carry out fatty acid synthesis occur with the intermediates tethered to the FAS. The intermediates are covalently linked by thioester bonds to the -SH group of the long 4'-PP sidearm which facilitates translocation of intermediates from one catalytic center to the next in sequence until the multiple steps of long-chain fatty acid synthesis are completed. Each round of elongation lengthens the chain by two carbons, a process that is repeated 7 or 8 times for the synthesis of a 16- or 18-carbon-containing fatty acids.

The process is initiated by the transfer of an acetyl group to 4'-PP from acetyl-S-CoA. The acetyl group linked to 4'-PP serves as the primer onto which the long-chain fatty acid is built. Malonyl units from malonyl-CoA, which serve as the chain-elongating group, condenses with the acetyl-primer concomitant with decarboxylation to produce a four-carbon

intermediate that then undergoes two reductive and one dehydration steps. Successive malonyl groups are transferred to FAS from malonyl-CoA to provide the basic units for successive steps in the elongation process. The terminal step is catalyzed by a thioesterase releasing the long-chain fatty acid product.

Glossary

Cathepsins Lysosomal proteinases, mostly thiol-dependent proteinases of the papain family. They are present in multiple forms of which cathepsin K seems to be the most potent collagen-cleaving enzyme.

Collagen Major structural proteins of the body with type I being the most abundant protein in soft connective tissue and bone. The major fibrillar collagens (types I, II, and III) provide much of the structural framework for soft connective tissues, cartilage, and bone. They are generally highly resistant to proteolysis.

Collagenase Enzyme capable of cleaving native collagen under specified conditions (temperature and pH).

Knockout mouse Mouse rendered deficient for a selected gene by targeted inactivation of the encoding locus in embryonic stem cells, subsequent transmission of the trait to the germ line and breeding of the trait to a homozygous state.

Matrix metalloproteinases (MMPs) A group of zinc endopeptidases (metzincins) characterized by zinc-binding VAAHEXGHXXGXXH amino acid consensus sequence in the catalytic domain and activation by a so-called cysteine switch. This residue is harbored in the latency-conferring prodomain that is proteolytically cleaved upon activation. This group of enzymes does not include a disintegrin and metalloproteinases (ADAMs), which contains a characteristic disintegrin domain.

What Is a Collagenase?

The term collagenase was first used by Gross and Lapiere in their 1962 description of an activity released from cultured tissue explants of involuting tadpoles, which dissolved otherwise highly proteinase-resistant, reconstituted collagen fibrils. This was a groundbreaking finding. It was the first demonstration of the existence of an activity operating at neutral pH that was fully capable of dissolving and cleaving native collagen fibrils. It marked the beginning of an exciting period of discovery that led to the identification of a large number of distinct matrix metalloproteinases (MMPs), almost six to seven in number with collagen-cleaving capabilities under various *in vitro* conditions (Table 1).

Original Definition of Collagenases

The unique resistance of native collagen molecules to proteolysis is a result of the tightly wound, semirigid triple helical structure. However, the resistance is only relative and not absolute. Generally, one of the two tests was applied to ascertain whether an enzyme or an activity represented a true collagenase: (1) ability to dissolve reconstituted type I collagen fibrils in the temperature range 35–37 °C and/or (2) ability to cleave type I collagen in solution at neutral pH in the temperature range 15–25 °C into two distinct and recognizable 1/4–3/4 fragments (classical collagenase signature cleavage pattern). That the 3/4–1/4 cleavage site is actually utilized *in vivo* was elegantly shown by Robin Poole and co-workers by neo-epitope immunohistochemistry which convincingly identified collagen molecules in several tissues, which were cleaved at this particular site. Since a number of collagenases cleave this site, the mere detection of this neo-epitope does not necessarily identify any single enzyme responsible for the cleavage. Despite this, the 3/4–1/4 cleavage

products are highly useful hallmarks in the analysis and characterization of collagenase activity.

Several lines of evidence support the notion that the collagenase-sensitive cleavage site is subject to local unwinding and therefore constitutes a site of minor resistance. For example, type III collagen has an arginine substitution in the susceptible region, and is readily cleaved by trypsin producing a 3/4–1/4 pattern. However, the collagenase-sensitive site in the $\alpha 1$ chain of type I collagen can be mutated in mice without yielding an acute collagen indigestion phenotype. The modification leads to a progressive fibrosis, but at a rate indicating that the collagen molecule is cleaved with some efficiency elsewhere. The term collagenase based on site specificity may thus be only partially applicable and may in effect obscure the fact that collagen is cleaved at other sites by collagenases, which do not qualify for this designation based on the criteria of generating 3/4–1/4-specific cleavage products.

Revised Definition of Collagenases

Based on the observations outlined above, the original definition of a collagenase will therefore have to be revised and broadened to also accommodate other proteinases such as cathepsin K, which clearly is a potent collagen-cleaving enzyme and yet utilizes other cleavage sites in the triple helical region and functions at acidic pH. The ability to cleave native type I collagen in solution within the temperature range 15–25 °C at either neutral or acidic pH, or completely dissolve native or reconstituted collagen fibril matrices at 35–37 °C, still appears to be a valid requirement. It is now increasingly being recognized that type I collagen-cleaving ability *in vitro* does not necessarily mean that the enzyme in reality functions as a collagenase *in vivo*. In fact, the assay conditions ordinarily used to assess the collagenolytic activity of putative

Table 1 Fibrillar collagenases (proteinases with activity against fibrillar collagens)

Enzyme	Other name	Classification	Species
MMP-1	Collagenase-1, interstitial collagenase	Matrix metalloproteinase	Widely expressed except in rodents
McolA		Matrix metalloproteinase	Mice
MMP-2	Gelatinase, type IV collagenase	Matrix metalloproteinase	Widely expressed
MMP-8	Collagenase-2, PMN collagenase	Matrix metalloproteinase	Widely expressed
MMP-13	Collagenase-3, interstitial collagenase	Matrix metalloproteinase	Widely expressed
MMP-14	MT1-MMP	Matrix metalloproteinase	Widely expressed
MMP-18	Collagenase-4	Matrix metalloproteinase	Frog
Cathepsin K		Acidic thiol proteinase	Widely expressed

collagenases may rarely, if ever, entirely mimic the conformation and configuration of the substrate when it is associated with multiple other components of the extracellular matrix (ECM) and packed to densities rarely achieved in a cell-free system. Conversely, an argument may also be made that enzymes displaying little collagenolytic activity *in vitro* may conceivably be potent collagenases *in vivo*, if by association with other ECM macromolecules, the collagen molecules are made more readily available for cleavage. Standard enzyme kinetic assays measuring substrate conversion are often ill-suited to account for reactions, which take place in a two-dimensional, diffusion-restricted environment such as a cell-membrane or a solid-substrate surface. For collagenolytic enzymes with trans-membrane spanning domains, a solution-based assay can obviously change the basic environmental properties under which a molecule ordinarily works, and molecules commonly recognized as secreted exert their function in close proximity to the peri-cellular (solid phase) environment. In addition, the actual enzyme-to-substrate ratio *in vitro* may not adequately mirror that which exists *in vivo*. It may therefore be necessary to revise the definition collagenase and assign the term only to enzymes for which there is some evidence, for instance, from naturally occurring mutations or gene ablation studies, that they truly function to cleave collagen *in vivo*.

The Collagenases

Within a few years of the discovery of tadpole enzyme, similar activities were identified in many vertebrate species including humans. Among these were an enzyme from polymorphonuclear neutrophil (PMN) leukocytes that later turned out to be a genetically distinct collagenase (MMP-8). Gelatinase A/type IV collagenase (MMP-2) was also identified early on and recognized as a probably distinct and separate activity because of its ability to cleave type IV collagen and gelatin. However, it was not recognized until Aimes and Quigley's important study in 1995 that MMP-2 can also be a genuine type I collagen-specific collagenase once the inhibitor TIMP-2, with which it is often complexed, is removed. This finding raises the question whether, and under what conditions, TIMP-2-free proMMP-2 exists *in vivo*? MMP-13 or collagenase-3 is found in both humans and rodents and displays partial homology to the human interstitial collagenase, MMP-1. It was thus originally thought to be the rodent ortholog of MMP-1, but turned out to be a genetically distinct collagenase capable of also dissolving the

otherwise highly resistant and slowly cleaved type II collagen. Surprisingly, rodents appear to express MMP-13 in most places where MMP-1 is expressed in humans, thus suggesting that it is a functional equivalent. Yet a closer rodent ortholog of human MMP-1 called Mcol-A has been identified, but so far has been characterized only to some extent. Based on the initial analysis, Mcol-A appears to have some collagen-cleaving ability against type I collagen although the specific activity seems fairly low. A collagenase (MMP-18), which was distinct from MMP-1, MMP-13, and MMP-8, was discovered in the frog but no vertebrate ortholog has been identified. The first membrane-type MMP (MT1-MMP or MMP-14) was discovered in 1994 and, shortly after, it was shown to have collagen-cleaving activity at least *in vitro*. Later five additional membrane-bound MMPs were identified but it is not yet known whether they possess collagen-cleaving activity. Although most of the collagenases mentioned so far have been MMPs, it is, as previously mentioned, necessary today to include also the thiol cathepsin, cathepsin K. This potent collagen-cleaving enzyme is utilized in the phagocytic pathway of collagen degradation and in osteoclastic bone resorption, when mineralized type I or type II matrices are dissolved. Various collagenases display somewhat varying substrate preference against type I, type II, and type III collagens. Type I collagen is most readily cleaved by MMP-8 and MMP-14, while MMP-1 shows preference for type III collagen and MMP-13 for type II collagen.

Recent New Insights

The past decade has dramatically altered our view of the role of classical collagenases in normal growth and development. The advent of gene ablation techniques in combination with various mouse models has enabled detailed exploration of the biologic function of the individual collagenases *in vivo*. Unfortunately, MMP-1 cannot be subjected to this approach because it is not expressed in mice and no human mutations of MMP-1 have been characterized. Although a potent collagenolytic enzyme *in vitro*, the true role of MMP-1 *in vivo* may therefore not be known until a human null-mutation is discovered. No reports have emerged yet with regard to ablation of the weakly collagenolytic, putative murine MMP-1 ortholog, Mcol-A. MMP-2 has been knocked out, but the phenotype is very mild when considering that this enzyme is perhaps the most widely expressed MMP. It was subsequently shown that primary tumor mass and metastatic spread were significantly reduced

in MMP-2-deficient animals in two independent tumor models, but it is uncertain whether and/or how these observations relate to collagen degradation. So, at this point there is only limited evidence that MMP-2 indeed serves as a collagenase in mice. Adding confusion to this scenario, however, is the finding by Martignetti and co-workers of the first human MMP-mutation (in MMP-2), which yields a rather spectacular generalized osteolytic bone phenotype. It is dramatically different from that of the mouse but it does have features of a collagen indigestion phenotype. Recently, ablation of the PMN collagenase MMP-8 was reported. Interestingly, MMP-8 deficiency, particularly in male mice, resulted in a dramatic rise in 7,12-dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate-induced skin tumors, diminished inflammatory response, and chemokine processing, suggesting that an important protective role, conferred by MMP-8, had been lost. It is so far unresolved whether this effect is a function of the loss of collagenolytic activity by PMNs. An MMP-13-deficient mouse has been generated which shows widening of the growth plate presumably as a result of impairment of cleavage of collagen type II in this area. Moreover, osteoclast differentiation and activity are impaired (SM Krane, personal communication) and bone formation is increased. The phenotype is thus consistent with MMP-13 serving as a collagen-cleaving enzyme *in vivo*. MT1-MMP (MMP-14)-deficient mice display a profound and complex phenotype in which growth, development, and maintenance of multiple collagen-containing matrices (bone, skin, tendon, joints, and ligaments) are severely impaired due to the loss of an indispensable and uncompensated collagenolytic activity. Since the MT1-MMP knockout phenotype does not resemble those of either MMP-2 or MMP-13, it is highly unlikely that MT1-MMP functions primarily through the activation of these enzymes as has been suggested. Rather, MT1-MMP appears to serve as a highly effective collagenase in its own right *in vivo*. However, it is interesting to note that MT1-MMP displays somewhat weaker collagenolytic activity *in vitro* than, for instance, MMP-1. This finding again points to some level of disconnect between collagenolytic capacity *in vivo* and *in vitro*. In the case of cathepsin K deficiency, the predictions of collagenolytic impairment, however, do hold up *in vivo*. Mouse and human cathepsin K gene mutations give rise to pycnodysostosis in humans and osteopetrosis in the mouse consistent with impairment of osteoclast-mediated type I collagen cleavage. These findings help identify cathepsin K as the acidic collagenase required for the removal of type I and type II collagens from mineralized matrices, which can only be dissolved in an acidic environment. It is highly likely that cathepsin K also is responsible for the cleavage of soft tissue collagen fibrils in phago-lysosomes during the often-overlooked phagocytic pathway.

Conclusion

In the aggregate, recent findings have demonstrated that true collagenases as defined by their substrate specificity *in vivo* can be found in at least two different classes of proteolytic enzymes (MMPs and cathepsins). Moreover, it is now evident that not all predictions based on enzyme kinetics obtained *in vitro* hold up *in vivo*. Collagenases work in the complex environment of an ECM. Fortunately, the tools for characterization of enzyme substrate interactions have now entered an exciting new era, which offer multiple genetic approaches to elucidation of these questions. Based on such approaches we have already come to realize that seemingly identical enzymes can perform different roles depending on the species. With this knowledge in mind, the understanding of and search for the collagen-metabolizing enzymes should continue.

Glossary

Collagen fibrils Thin structures, 40–500 nm in diameter. Fibrils are assembled laterally into much larger fibers in tissues such as tendons.

Collagen monomer A protein containing a collagen triple helix.

Collagen triple helix A unique protein structure in which each of three chains with a (Gly–XY–)_n sequence is

coiled in a left-handed helix and the three chains are wrapped around each other in a more extended right-handed helix.

Procollagens The soluble precursors of fibrillar collagens that contain large, noncollagenous extensions of both ends of the long triple-helical domains.

The Signature (Gly–XY–)_n Sequence of Collagens

In the signature amino acid sequence of collagens, every third amino acid is glycine, the amino acid following glycine is usually the five-member ring amino acid proline, and the next amino acid is hydroxyproline. Therefore, the signature sequence is usually depicted as (Gly–XY)_n in which the X position is frequently proline and the Y position is frequently hydroxyproline. Under physiological conditions, three chains with the signature (Gly–XY–)_n sequence spontaneously associate into a three-stranded helix that is unique to collagens. The subclass of collagens that form large fibrils consists almost entirely of long (Gly–XY–)_n sequences tightly coiled into triple-helical structures referred to as collagen monomers. The long triple-helical monomers, in turn, spontaneously associate into long, highly ordered fibrils. In some tissues, the long fibrils associate laterally into thick fibers. The two steps in which (Gly–XY–)_n sequences assemble into triple-helical monomers and the triple-helical monomers assemble into fibers resemble the crystallization of small molecules (Figures 1 and 2). Each step is entropy driven by loss of surface water as the larger structure is formed, much as is seen in many crystallization processes. Also, as with crystallizations, each step involves first the slow formation of a small nucleus of a defined structure, and then rapid propagation of the nucleus to form a large structure in which the molecular architecture of the nucleus is extensively replicated. Glycine, the smallest amino acid, must be in every third position in the collagen triple helix because it occupies a very small space where the three chains come together. In addition, the hydrogens on the α -carbon of glycine allow it to form hydrogen bonds across the three chains. The closed-ring structures of the proline and hydroxyproline residues limit rotation of the polypeptide backbone, thereby providing rigidity to the structure.

Hydroxyproline residues, which are rarely found in other proteins, play a special role in the triple helix. The hydroxyl groups lock the slightly flexible ring of the amino acid into a conformation that further stabilizes the polypeptide backbone. Charged amino acids that occupy the X and Y positions in the repetitive (Gly–XY–)_n sequences point out from the center of

the triple helix. The orientation of the charged groups allows them to form salt bridges that bind each triple-helical monomer to surrounding monomers. Most of the monomers in fibrils are staggered one-quarter of their length relative to their nearest neighbors with short gaps between their ends. The gaps are readily seen by staining the surface of the fibrils and examining them by electron microscopy: each fibril has a cross-striated pattern in which the distances between the cross-striations correspond to about one-quarter of the lengths of the monomers. After assembly of the fibrils, the structures are further stabilized by a cross-linking enzyme that generates highly reactive aldehydes by deaminating some of the terminal amino groups on lysine residues that project out from the surface of the monomers. The aldehydes then spontaneously form covalent bonds that link most of the monomers throughout the width and length of the fibril. The result is a highly ordered structure with about the same strength as a steel wire. In essence, the signature (Gly–XY–)_n sequences contain essentially all of the information and driving forces needed to spontaneously generate the highly ordered fibrils and fibers that in some tissues can be several feet long.

The Two Subtypes: The Fibrillar and Nonfibrillar Collagens

The fibril-forming or fibrillar collagens contain long and uninterrupted (Gly–XY–)_n sequences (Figure 1(a)). They are among the most abundant proteins in nature, and the most abundant of the fibrillar collagens are referred to as types I, II, and III. They are similar in structure in that each contains three polypeptide chains (α -chains) with approximately 330 –Gly–XY– triplets. They are also similar in that the α -chains spontaneously self-assemble into similar triple-helical monomers and the monomers spontaneously assemble into fibrils. Type I collagen accounts for well over 50% of the dry weight of ligaments, tendons, and demineralized bone. However, the biological properties of the fibrils depend on the still-undefined forces that orient the fibers in tissues. For example, the type I collagen fibrils in ligaments and tendons are present in parallel

Figure 1 (a–f) Schematic for the structure of various collagens. Reproduced from Prockop DJ and Kivirikko KI (1995) Collagens: Molecular biology, diseases, and potentials for therapy. *Annual Review of Biochemistry* 64: 403–434.

bundles of thick fibers. In skin, they are randomly oriented in the plane of the skin. In many regions of bone, type I collagen fibrils form highly symmetrical concentric helical arrays around the Haversian canal through which capillaries pass. Type II collagen is very similar to type I collagen in structure, but it is found almost exclusively in cartilage, where it forms very thin fibrils that trap highly charged proteoglycans and water. The result is an arcade-like structure that makes cartilage highly resilient to compression. Type III collagen is also similar to type I collagen in structure and its spontaneous assembly into fibrils. Type III collagen is associated in relatively small amounts with type I collagen in many tissues, but, for reasons that are not apparent, it is particularly abundant in the aorta.

The family of collagen proteins also includes a large number of proteins referred to as nonfibrillar collagens because they contain either only short (Gly-XY)_n sequences or (Gly-XY)_n sequences that are interrupted by noncollagen sequences. As a result, the proteins do not assemble into highly ordered fibrils

(Figures 1(b)–1(f)). One important example of a nonfibrillar collagen is the type IV collagen, which is an abundant constituent of basement membranes (Figure 1(b)). The protein is a large trimeric monomer with multiple (Gly-XY)_n sequences that are interrupted by noncollagen sequences; it also contains large globular domains at both ends. The interruptions make the protein flexible, and the globular ends enable the protein to form flexible networks that bind multiple other proteins. The flexible networks bind epithelial cells and form the barriers that protect the organism from the external environment. Other nonfibrillar collagens are much less abundant and fulfill more specialized functions. Some bind to the surfaces of fibers formed by fibrillar collagens and help either to regulate the assembly process or to provide binding sites for cells or other components of the extracellular matrix. For example, type IX is a short collagen that is flexible because its (Gly-XY)_n sequences are interrupted by two noncollagenous sequences (Figure 1(c)). Type IX collagen binds to both fibrils of type II collagen and proteoglycans to provide one of the connecting links in the arcade-like structure of cartilage. Some nonfibrillar collagens contain very short (Gly-XY)_n sequences and triple-helical domains that serve primarily as extension rods for more interactive domains on the ends of the same proteins (Figure 1(f)).

Collagens and collagen-like proteins are abundant in many multicellular organisms. For example, they are very abundant in diverse invertebrates such as sponges and worms, including the worms found in deep-sea hydrothermal vents. The smallest collagens appear to be minicollagens that contain only 12–16 – Gly-XY– repeats, and that are found in the nematocysts with which hydra sting their prey.

The Need to Control the Self-Assembly of (Gly-XY)_n Sequences

Viewed with evolution in mind, the special properties of (Gly-XY)_n sequences can be seen to have a variety of different purposes. One of the most important of these purposes was to produce tough fibrils to hold together cells and thereby provide a means of developing multicellular organisms. However, it is clear that there had to be controls on the tendency of long polypeptides with repetitive (Gly-XY)_n sequences to spontaneously assemble into large fibers. In living systems, the assembly of fibrils cannot be allowed to occur prematurely. If they did, the fibrils would either destroy the cell synthesizing the protein or encase the cell in an impenetrable matrix. Also, the fibrils must be strong but not as rigid as crystals. Their flexibility is critical for most tissues. It is apparent, for these reasons, that the synthesis of collagens is an elaborate process in which a series of specialized enzymes modifies the polypeptide chains as they are assembled on ribosomes and then pass into the cisternae of the endoplasmic reticulum en route to the Golgi apparatus and secretion from the cell.

Why the Hydroxyproline?

One of the initial intriguing questions about collagens was why they contain large amounts of hydroxyproline, an amino acid

Figure 2 Schematic for the biosynthesis of a fibril-forming collagen. (a) Intracellular events that involve posttranslational hydroxylations and glycosylations, association of polypeptide chains, and folding of the triple helix. (b) Extracellular events that involve cleavage of the N- and C-propeptides, self-assembly of collagen into fibrils, and cross-linking of the fibrils. Reproduced from Prockop DJ and Kivirikko KI (1995) Collagens: Molecular biology, diseases, and potentials for therapy. *Annual Review of Biochemistry* 64: 403–434.

very rarely found in other proteins. Early isotope studies demonstrated that after administration of labeled proline to rodents, both labeled proline and hydroxyproline were present in proteins isolated from the animals. After administration of labeled hydroxyproline, however, essentially no labeled hydroxyproline was recovered. Therefore, long before the genetic code was solved, it was apparent that the hydroxyproline in collagen was introduced by an event that did not occur during the initial assembly of the protein but that occurred as a posttranslational event. These observations led to the discovery that the hydroxyproline in collagens was synthesized by prolyl hydroxylase, an enzyme that specifically hydroxylates proline in the Y position in peptides with $(\text{Gly-XY-})_n$ sequences. The question of why hydroxyproline is introduced in this manner was resolved by demonstrating that if prolyl hydroxylase is inhibited, cells synthesize complete collagen polypeptide chains that cannot fold into a collagen triple helix unless the protein is cooled to about 15°C below body temperature (Figure 2). The protein folds into a triple helix at body temperature only if about 100 proline residues in each of the 1000-amino-acid-long α -chains of fibrillar collagen are hydroxylated to hydroxyproline. After the protein folds into the triple-helical conformation, prolyl hydroxylase can no longer modify it. In effect, prolyl hydroxylase titers the hydroxyproline content of the proteins so that it folds at body temperature. Remarkably, the protein is not secreted from cells in significant amounts until it acquires the requisite content of hydroxyproline and folds into a triple helix. This elaborate system is one means of preventing the protein from folding too early in the

biosynthetic process. The process by which prolyl hydroxylase gradually titers the hydroxyproline content of collagens serves a second function of ensuring that collagen fibrils are flexible. The monomers are secreted by cells before all the Y position proline residues are fully hydroxylated and before the molecule is a completely rigid rod. Instead, regions of the protein that have low contents of proline and hydroxyproline tend to breathe in the sense that they rapidly fold and unfold. Because the monomers are not rigid triple helices, the fibrils they assemble into are not fully crystalline and remain flexible. As might be expected, monomers for fibrillar collagens from organisms with body temperatures ranging from 18 to 40°C completely unfold at about 4°C above the body temperatures of the organisms. The fibrillar collagens from organisms with varying body temperatures have different amino acids found in the X and Y positions that in part explain their different stabilities, but each begins as an unfolded protein that folds as its hydroxyproline content is titrated to a critical level by prolyl hydroxylase. After the monomers assemble into fibrils, the lateral interactions of protein make the triple helix stable to about 16°C above body temperature.

Other Levels of Control

The process of fibril assembly by fibrillar collagens is also controlled at another step. The monomers are first synthesized as larger precursors that are known as procollagens. The procollagens have large noncollagenous domains at both ends that keep

the monomers soluble and prevent them from self-assembling until the domains are cleaved by proteinases found outside the cells (Figure 2). Therefore, the proteinases help to regulate the formation of fibrils. In addition, the first fibrils formed begin to accumulate other proteins and components of the extracellular matrix on their surfaces that prevent fusion of the fibrils into large fibers. The rate at which these components are removed provides still another control on the formation of fibrils and fibers.

One Surprise: The Enzymes Involved in Collagen Synthesis Have Other Functions

The biosynthesis of collagen involves processing by a series of separate enzymes that have a number of unusual properties (Figure 2). Because the enzymes carried out processing steps not seen in the synthesis of other proteins, it was initially felt that the enzymes were uniquely dedicated to production of collagen. Subsequently, it became apparent that several of the enzymes had important additional functions. For example, prolyl hydroxylase is unusual among the small number of enzymes that modify proteins in that it requires unfolded peptide substrates. It is also unusual in that it specifically hydroxylates prolyl residues in the Y position of $-\text{Gly-X-Pro}-$ sequences. In addition, it is unusual in that the reaction uses iron, molecular oxygen, and ascorbate as well as α -ketoglutarate that is oxidatively decarboxylated to succinate in the reaction. It was surprising, therefore, that cloning of the genes for the two subunits of the enzyme revealed that the β -subunit is identical to protein disulfide isomerase, an enzyme that is required to ensure the correct formation of disulfide bonds during the synthesis of a large number of noncollagen proteins. Perhaps even more surprising was the discovery of three similar but different prolyl hydroxylases that hydroxylate a single proline residue in hypoxia induction factor, a protein that triggers the response of tissues to ischemia. The proline residue in hypoxia induction factor must be hydroxylated for the protein to be degraded by proteasomes. One consequence of this discovery is that inhibitors of prolyl hydroxylase initially designed to limit the excessive deposits of collagen found in scars also increase tissue levels of hypoxia induction factor, thereby enhancing their response to hypoxia. Inhibitors of prolyl hydroxylase therefore appear to provide a new strategy for the treatment of diseases such as anemias that are now treated with erythropoietin.

Similar surprises have been encountered with the proteinases that cleave the amino acid extensions on the ends of the procollagen precursors of fibrillar collagens and that keep the proteins from prematurely assembling into collagen fibers. The proteinase that cleaved the large C-terminal globular domains was a large zinc metalloproteinase with an unusual specificity for the similar but different sequences in the cleavage sites for the precursors of types I, II, and III collagens. Therefore, it seemed reasonable to assume that it was a protein with a unique function. Subsequent work demonstrated that the same enzyme was essential for processing a component of basement membranes (laminin-5) and for processing the enzyme (lysyl oxidase) that generates the aldehydes that form

the covalent cross-links in fibrils of both collagen and elastin. Even more surprising was the discovery that isoforms of the same enzyme are essential in completely unrelated processes in early embryonic life: they establish a gradient for dorsolateral development by cleaving inhibitors of morphogenic proteins (decapentaplegic/BMP-2/BMP-4).

Evolutionary Origins and Selective Pressures on $(\text{Gly-X-Y})_n$ Sequences

The manner in which $(\text{Gly-X-Y})_n$ sequences arose and were distributed across biology during evolution cannot be defined any more accurately than many other aspects of evolution. One clue seemed to come from the observation that the genes for the major fibrillar collagens have an unusual structure: most of the codons for the triple helix were found in short exons that were 54 bases long and coded for 18 triplets of $(\text{Gly-X-Y})_n$ sequences. Therefore, it appeared that evolutionary pressures had trapped the 54-base exon and replicated it to produce genes for many different collagens. Unfortunately, this attractive hypothesis was not substantiated by data on other collagen genes in which the exons are also relatively short, but the 54-base motif is not a common theme. Independent evidence on the selective pressures on the structure of collagens and the biosynthetic pathway is provided by data on mutations found in patients and a few animals with genetic diseases. Studies on mutations in fibrillar collagens confirmed that the presence of glycine in $(\text{Gly-X-Y})_n$ sequences is critical. Hundreds of mutations that substitute an amino acid with a bulkier side chain for a single glycine distort the triple helix or prevent it from folding. As a result, the mutations produce a large series of diseases of bone, cartilage, blood vessels, and other tissues. Most of the mutations produce severe and rare diseases in children; a few produce variants of common diseases such as osteoporosis or osteoarthritis. The selective pressure for maintaining the signature acid sequences explains why the mutations in collagens differ only slightly from those in organisms that have evolved separately for millions of years. Mutations in the proteinase that cleaves the N-terminal extension on two fibrillar procollagens (types I and II) also produce severe diseases of the skeleton, skin, and other tissues. However, no mutations have been found in either prolyl hydroxylase or the proteinase that cleaves the C-terminal extensions on the procollagen precursors of fibrillar collagens. Such mutations are presumably lethal early in embryonic life.

Summary

The impressive ability of $(\text{Gly-X-Y})_n$ sequences to spontaneously undergo self-assembly has been used time and again in biology to provide structures with a variety of important features. However, biological systems need safeguards to control the spontaneous self-assembly of the $(\text{Gly-X-Y})_n$ sequences. The principal safeguard is a biosynthetic pathway in which the protein is assembled through a series of complex steps that prevent premature self-assembly and modulate how perfectly the protein crystallizes.

Color Vision

G H Jacobs, University of California, Santa Barbara, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Color vision The ability of an animal to reliably discriminate between lights that differ only in their spectral energy distributions.

Opsins G-protein-coupled receptors embedded in the membranes of photoreceptor cells. They are light sensitive and mediate the conversion of photons to neural signals.

Polymorphism The presence of two or more different phenotypes within the population of a species.

Spectrally opponent cells Cells in the visual system that signal the difference in absorption rates of two or more types of cone photopigments, thus providing the neural substrate for color vision.

Univariance Describes a response property of photopigments wherein they generate an equal-sized signal for every photon that is absorbed irrespective of its wavelength.

Introduction

Light reaching the eye from various locations in the environment can vary both in its distribution of spectral energies and in its overall intensity (total photon flux). Color vision is defined formally as the ability of an animal to make reliable discriminations based solely on former, irrespective of values of the latter. In perceptual terms this means that in tests to establish and characterize color vision potential cues to discrimination based on variations in object brightness or lightness are rendered irrelevant. A familiar example of the application of this strategy is exemplified by the various plate tests that are often used to test human color vision. These plates are composed of an array of small, nonoverlapping circles that vary in size, lightness, and spectral reflectivity. In the test the viewer is asked to identify an object appearing in the plate, typically a numeral or a geometric form, when the presence of that object is consistently defined only by its shared property of color. A strong implication of this definition of color vision is that any visual system capable of supporting that capacity must be so configured that it can disambiguate joint variations in the intensity and wavelength of light. Here we consider the biological elements making it possible.

Photoreceptors

In vertebrate retinas two types of photoreceptors, the familiar rods and cones, serve to provide the initial active stage in the visual process. Both are delicate and densely packed, elongate cells positioned at the outermost portion of the retina with their long axes aligned with the incoming light (**Figure 1(a)**). With few exceptions all vertebrate retinas contain both rods and cones, but the two types show significant variation across species in their overall numbers, their relative representation (cone/rod ratios), and their spatial distributions across the extent of the retina. It has long been appreciated that, in general, rods and cones subserve different domains of vision, cones being linked to daylight (photopic) vision providing the information required for high spatial and temporal resolution, as well as color vision, while rods, with their higher sensitivity and lower inherent noise properties, support vision when ambient light levels are generally low

(scotopic). Although rods are usually associated with achromatic vision, both types of photoreceptors can contribute to vision during those transitional twilight periods between these two light regimes (mesopic); under these conditions rods have been shown capable of making some contributions to color vision. Such instances are not considered here further.

Cone Photopigments

Cone photopigments are densely packed in a stack of membranous disks that make up the outer segments of the photoreceptors (**Figure 1(a)**). The total pigment density, and thus its capacity for trapping incoming photons, depends on the packing density of the photoreceptors and the lengths of the outer segments and these may vary considerably both within and across retinas. At their best, cones operate with high efficiency; for example, in the central part of the human retina cone pigment can absorb as many as 75–80% of all incident photons. These pigments are composed of a protein (opsin) linked to a chromophore that is an aldehyde of vitamin A. Opsins are members of a large family of G-protein-linked receptor molecules in the case of opsins being constituted as a chain of ~350 amino acids embedded in a lipid membrane in the form of seven transmembrane α -helical palisades with retinal bound via a Schiff base linkage to a lysine residue in the seventh helix (**Figure 1(b)**). Vertebrate photopigments are constructed from either of two chromophores – retinal or 3-dehydroretinal. Although there are some notable exceptions, the latter are generally found in freshwater fish, amphibians, and reptiles, whereas retinal is common in animals living in marine and terrestrial environments and is the only chromophore used to produce photopigments in all birds and mammals. From a functional point of view, replacing retinal with 3-dehydroretinal has the effect of displacing the wavelength of maximum absorbance (λ_{max}) of the photopigment toward the longer wavelengths, the magnitude of the displacement being greater for those pigments that have maximal absorbance in the longer wavelengths.

Absorption of a photon of light causes the chromophore to isomerize from an 11-*cis* to an all-*trans* configuration initiating a cascade of molecular events that result in a change in the flow

Figure 1 (a) Sketched version of the vertebrate cone photoreceptor with the normal pathway of incoming light indicated by the arrow. The outer segment (OS) consists of a stack of membrane-limited disks which contain the photopigment. The synaptic terminal (at the base of the cell) is the location where photoreceptors deliver signals to other retinal cells. (b) Schematic representation of the M/L primate cone opsin. The 364 amino acids are drawn as small circles. The three residues responsible for the spectral tuning of these pigments in New World monkeys are numbered (180, 277, and 285). Dimorphic amino acid substitutions at these sites shift the absorption spectrum of the pigment by the amounts and direction listed inside the box. The chromophore attachment site is at residue 312. (c) Absorption curve for an M/L cone photopigment. Various combinations of residue substitutions at the three indicated sites shift the absorption properties of the M/L pigments in New World monkeys so as to allow them to occupy five discrete spectral locations (all within the range indicated by the bar). Reproduced from Jacobs GH (2009) Cone photopigment evolution. In: Squire LR (ed.) *Encyclopedia of Neuroscience*, vol. 3, pp. 59–65. Oxford: Academic Press, with permission from Elsevier.

of ionic current across the cell membrane. This cascade occurs rapidly and entails a considerable amplification of signal strength. This signal spreads along the extent of the photoreceptor membrane and modulates the release of the neurotransmitter glutamate from cone terminals, thus providing an input signal to second-order cells in the retina. Retinal absorbs maximally in the short wavelengths (~ 440 nm) but, when bound to an opsin, the absorbance spectrum is shifted. The magnitude and direction of this shift, and thus the $\lambda_{\max}$ of photopigments, depend on the structure of the particular opsin. When properly scaled, the shapes of the absorbance spectra of all photopigments are very similar and so are conventionally characterized according to their $\lambda_{\max}$ values (Figure 1(c)). Photoreceptors behave univariantly meaning that once absorbed every photon yields an identical sized signal. Note also that photopigments display a secondary sensitivity peak (β -band) in the short wavelengths (Figure 1(c)).

Cone Opsin Genes

The cones of the human retina contain any of three separate classes of cone photopigment. The genes specifying these three opsins were first isolated and sequenced about 25 years ago and, as had long been apparent from studies of the inheritance of human color vision defects, genes specifying the opsins for two of these cone pigments (having $\lambda_{\max}$ at ~ 530 and 560 nm and conventionally called M and L, respectively) were localized to the X-chromosome (Xq28) where they are positioned in a head-to-tail tandem array. Each of these genes specifies an opsin made up of 364 amino acids. Having a recent common origin, the amino acid sequences for the M and L opsins are 96% identical. The gene for the opsin of the third type of human cone pigment (with $\lambda_{\max} \sim 420$ nm and termed S) was mapped to chromosome 7 (7q31–32). The S-opsin consists of ~ 350 amino acids and, reflective of the fact that the genes are

more distantly related, has a sequence identity to those for M and L of only about 40–45%.

In recent years opsin genes have been isolated and characterized for many other species (200 or more vertebrate species along with many invertebrates thus far) and that number continues to grow rapidly. This sequence information can be accessed at a website maintained by the National Center for Biotechnology Information (NCBI). These data have fostered the derivation of direct correlations between opsin sequences and photopigment absorption spectra, thus providing critical links between opsin genes and visual function. One major conclusion is that the spectral positioning of the absorption spectra of photopigments is controlled at a small number of critical locations in the opsin structure. A recent estimate concludes that the spectral positioning of all vertebrate photopigments involves changes at no more than a total of 30 different residues and within any subgroup of vertebrate photopigments that number is considerably more restricted. For example, the M/L cone photopigments of New World (platyrrhine) monkeys are polymorphic being positioned at any of five different $\lambda_{\max}$ values between ~530 and 560 nm. Those variant spectral positions reflect dimorphic amino acid substitutions at only three opsin locations (Figure 1(b)). These same three sites are also implicated in controlling the spectral positioning of the M/L photopigments in all the primates and, indeed, across all mammals only five amino acid sites are linked to shifts in absorption spectra over this region of the spectrum.

Large-scale comparisons of opsin gene sequences obtained from many species show that all vertebrate photopigments can be classified as belonging to five paralogous groups (i.e., sharing a common ancestry). An opsin gene family tree illustrating this fact is shown in Figure 2, which incorporates results obtained from a least one representative of each of the five major vertebrate groups. In total, these opsin genes code for photopigments whose $\lambda_{\max}$ values span a range from about 360 to 620 nm. Genes from one of the five groups (Rh1) are consistently linked to pigments expressed in rod photoreceptors; the other four families yield cone pigments. Note that genes from all five families (termed LWS, Rh2, Rh1, SWS2, and SWS1) yield pigments encompassing different spectral ranges and that there is some overlap in the achieved $\lambda_{\max}$ values across the various families. An additional important fact (Figure 2) is that representative birds, reptiles, and fishes may have pigments drawn from each of the four cone opsin gene families that is not true for either the amphibian (newt) or the two mammals (mouse and human) represented in the figure. Amphibians lack Rh2 genes, while humans, like all other eutherian (placental) mammals, derive cone pigments from only two of the families (SWS1 and LWS).

Linking Photopigments, Nerve Signals, and the Dimensionality of Color Vision

The univariant property of photopigments noted previously implies that a retina containing only a single type of photopigment is incapable of providing the information necessary to support color vision and, indeed, tests run on such animals show that they lack color vision. On the other hand, light reaching the retina that contains some spectral variation will inevitably

Figure 2 Opsin gene family tree. Indicated are representative contemporary species that draw their pigments from each of the five gene families (LWS, Rh2, Rh1, SWS2, and SWS1). The total range of $\lambda_{\max}$ values for pigments derived from genes of each of the families are listed to the right. These values are appropriate for photopigments that utilize the chromophore retinal. Reproduced from Jacobs GH (2009) Cone photopigment evolution. In: Squire LR (ed.) *Encyclopedia of Neuroscience*, vol. 3, pp. 59–65. Oxford: Academic Press, with permission from Elsevier.

be differentially absorbed by two types of photopigment, and that difference will be maintained irrespective of the overall intensity of the light. Thus, a nervous system that allows a comparison of signals emerging from two types of photoreceptors containing different photopigments can provide the substrate for color vision. Such an arrangement exists in the retinas of all vertebrate animals that are known to have color vision. Although the exact details of the neural circuitry to allow this show variations from species to species, in every case signals derived from one class of cone are merged with signals derived from the second class of cone onto recipient cells in a push/pull, excitatory/inhibitory fashion. Cells of this type, typically called spectrally opponent, effectively code the magnitude of the difference in absorption of the two cone pigments for any particular spectral stimulus.

As an example of this arrangement, consider the case of the human retina with its three classes of cone photopigment. Outputs from cones containing M and L pigment are combined in spectrally opponent cells, thereby generating a signal that is, effectively, L–M. Such signals are known to support color discriminations over the middle to long wavelengths and the emergent dimension of color vision is thus termed (for our species) red–green. If there are only two types of cone pigments and a single type of spectrally opponent cell, the system supports a single dimension of color vision (dichromatic). The human retina contains a third type of photopigment (S) and a separate set of neural connections in the retina allows the emergence of a second class of spectrally opponent cells – in this case involving signals drawn from all three cone classes in a combination that is effectively S – (M + L). This

allows an additional dimension of color vision, called yellow–blue in humans, and in conjunction with the red–green system renders humans trichromatic. Additional dimensions of color vision may emerge in animals whose retinas contain additional types of cone pigment and spectrally opponent cells.

Of course, color vision encompasses much more than just being able to make simple discriminations between spectrally variant stimuli (e.g., we link color percepts to surfaces and objects, use color as a source of information about the quality of objects and locations in the environment, etc.). All these operations are supported by additional neural processing that occurs along the projection pathways into the visual brain and beyond.

Evolution of Color Vision

Comparisons of gene structures have yielded reasonable agreement on a likely phylogenetic scheme for the evolution of the five vertebrate opsin gene families (Figure 2), but it is still uncertain as to when these events occurred and what functional consequences supported their evolution. Estimates based on the rate of gene divergence indicate that the four opsin cone classes must have emerged very early in vertebrate history, perhaps more than 500 million years ago (mya). This estimate finds support in the linked facts that is also about the time when jawless and jawed vertebrates diverged and that modern descendants of both lineages are known to have representation from all four cone gene classes. From similar kinds of observations, it appears that the Rh1 gene family (specifying rod photopigments) appeared later, probably as a result of a duplication of ancestral Rh2 cone opsin genes. The strong functional implication from this is that rods are a secondary major adaptation for vertebrate sight that have emerged as a specialization for supporting vision at low light levels. Although all four cone opsin gene families have been maintained in modern fishes, birds, and reptiles, both amphibians and mammals have each lost representation from these gene families. In the case of the amphibians, Rh2 genes are absent probably having been lost early in the evolution of this group.

A separate scenario for the evolution of photopigment genes in mammals is sketched in Figure 3. Note that no mammals have representation from the Rh2 gene family indicating that family was lost very early in mammalian history. An SWS2 cone

Figure 3 Schematic illustration of the pattern of photopigment loss and retention believed to have occurred during the evolution of mammals. The X's indicated the loss of photopigment types due to a loss of a gene family. Further details of this pattern are described in the text.

pigment gene has been detected in contemporary monotremes (platypus, echidna), but not in any of the marsupials or eutherian mammals, implying that the SWS2 gene family was lost prior to the time at which the latter two groups diverged from the monotremes (~ 160 – 170 mya). SWS1 cones survive in marsupials and eutherians but are absent in monotremes so that loss must be specific to the monotremes. All mammals retain representation from the LWS cone opsin gene family. Many species from one family of mammal, the primates, have acquired two or more representatives from the LWS gene family. Features of the primate arrangement are considered separately below. The circumstances that surround these various losses of opsin gene families have not been established, but there are some speculations: for example, one idea is that these all occurred during that early period when mammals were predominantly nocturnal and were thus perhaps subject to diminished adaptive pressures to maintain cone pigments given that cone operation provides predominant support for daylight vision.

The most common change to occur during the evolution of cone pigments involved not the addition or loss of gene families but rather shifts in the absorption spectra of the cone pigments. Such shifts have mostly come about as the result of residue changes at critical tuning sites in the opsin. For example, the ancestral SWS1 cone pigment in mammals is believed to have had $\lambda_{\max}$ in the ultraviolet, at ~ 360 nm. Although some contemporary mammals have retained this ultraviolet (UV) pigment (e.g., mouse and rat), in most mammalian lineages the SWS1 pigment was shifted into the visible wavelengths where it peaks, depending on the species, somewhere in the range ~ 420 – 450 nm. Pigment peak shifts of this type are functionally important as they can equip an animal to more efficiently harvest photons in some particular spectral band, thus supporting new behavioral repertoires or allowing the exploitation of new photic environments. In their interactions with signals derived from other pigment types, shifts in the absorption spectra will also alter the nature of derived color vision. It seems clear that across the full range of vertebrates such cone pigment peak shifts have occurred very frequently.

Given the known linkages between cone opsin genes, cone photopigments, and the dimensionality of color vision in some contemporary species, it is tempting to conclude that the evolutionary history of the cone opsin genes is also that for color vision. However, one should be cautious about such jumps because more is required to support color vision than just the presence of multiple types of cone opsin genes; for example, these genes have to be expressed in sufficient numbers of photoreceptors and the outputs from them have to be actively contrasted in order to yield color vision. Because of these additional organizational requirements, so far mostly unevaluated, we cannot be absolutely certain that the early emergence of multiple types of cone pigments necessarily implied a similar early emergence of elaborate color vision. Despite these reservations, it is nevertheless true that multiple types of cone pigments appeared early in vertebrate history and that arrangement has been maintained in various guises throughout the evolution of vertebrates. Those facts make it seem likely that a capacity for color vision has also been present throughout the long history of vertebrates and, given that, there is also strong support for the idea that color vision contributes significantly to survival in many different types of animal.

Primate Color Vision

Primate color vision is unique. Like other mammals, the earliest primates (dating to ~80–90 mya) were nocturnal and believed to have two types of cone pigment and dichromatic color vision. However, as primates subsequently diverged many acquired diurnal lifestyles supported by a variety of visual system alterations to enhance cone-based vision. Among the changes were significant improvements in color vision.

One signal event in the evolution of primate color vision occurred uniquely in the catarrhine primates (humans, apes, and Old World monkeys). About 35 mya the X-chromosome opsin gene duplicated. This added a second X-chromosome cone opsin gene which was subsequently altered in structure to encode a second LWS-based pigment (Figure 2) and that, in turn, set the stage for an added dimension of color vision making trichromatic color vision a routine capacity in all contemporary catarrhines. Most New World monkeys have followed a different path to enhance color vision. As noted earlier, many of these monkeys have highly polymorphic color vision. The polymorphism is based on the presence of multiple (usually three) alternative versions (alleles) of the X-chromosome LWS opsin genes each allele coding for a pigment having different spectral absorption properties (Figure 1). Since male monkeys have only a single X-chromosome, they get any one of the three versions of the LWS opsin gene and in conjunction with the SWS1 autosomal opsin genes have two cone pigments and dichromatic color vision. Females have two X-chromosomes so individuals that are homozygous at this gene locus also have any of the three M/L pigments and dichromatic color vision; however, heterozygous females have two different LWS opsin genes yielding a total of three cone pigments endowing them with trichromatic color vision. The polymorphic gene arrangement of the New World monkeys thus produces a rich array of individual differences in color vision. The third large group of contemporary primates, the more primitive strepsirrhines (lemurs, bushbabies and the like), shows considerable species variations in their opsin gene and color vision arrangements such that although some gain a polymorphic trichromacy of the sort just described, most have dichromatic color vision or they lack color vision entirely.

Humans normally have two different X-chromosome opsin genes supporting trichromatic color vision, but there are well-studied polymorphisms that result in dramatic individual variations in human color vision. Of these, the most familiar is red/green color blindness. About 2% of all Caucasian males have only a single photopigment absorbing in the middle to long wavelengths and so have dichromatic color vision. This defect apparently arose from an unequal meiotic recombination event. Since the two cone opsin genes are adjacent

to one another on the X-chromosome, such an unequal recombination can result in the production of an X-chromosome that has only a single opsin gene; since males have only a single X-chromosome such individuals will produce only a single type of M/L photopigment and become dichromatic. This same condition is much rarer in females simply because they have two X-chromosomes and thus have to be homozygous for this same alteration in order to have only a single M/L pigment. There are even more frequent red–green color vision variations where unequal recombination led not to a loss of a gene but rather to alterations in gene structures that shift the absorption spectrum of the second pigment. This too will produce clear changes in color vision that are also principally male afflictions. It is curious that color blindness, a condition reasonably common among humans, is effectively absent in all other catarrhine primates. To date there are no very satisfactory explanations for this difference.

Glossary

Site-specific recombinase The proteins that catalyse site-specific recombination reactions. These are named by the type of DNA rearrangement they mediate, that is integrase, resolvase, invertase, or transposase.

Site-specific recombination DNA breakage and reunion reactions that occur at specific DNA sequences.

Overview

Site-specific recombination systems mediate certain types of genetic exchange in bacteria that are important for growth, adaptation, and evolution. Mobile genetic elements such as phages, plasmids, and transposons, frequently encoding antibiotic resistance determinants or virulence genes, require site-specific recombination systems for their maintenance and/or cell-to-cell movement. Most bacteria rely on site-specific recombinases for the stable maintenance of chromosomes, ensuring that each of the daughter cells receives one copy of the chromosome. Site-specific recombination systems are also used to control gene expression. The recombinases fall into one of two protein families, the serine and the tyrosine recombinases, named after the amino acid residues that transiently become covalently linked to the DNA substrates during recombination. The two families are mechanistically and evolutionarily distinct and mediate precise and highly controlled DNA rearrangements. Despite there being only three outcomes of site-specific recombination, DNA integration, resolution (excision), and inversion, the control mechanisms used by different recombinases vary enormously.

The Biology of Conservative Site-Specific Recombination

The first description of a site-specific recombination reaction was by Allen Campbell, who proposed that the phage lambda prophage attaches to the *Escherichia coli* genome during the lysogenic growth cycle. Campbell's idea, which was later proved to be an important principle for most temperate phages, was that the host and the circularized phage genomes each have an attachment site, *attB* and *attP*, respectively, where a single crossover integrates the phage genome so that it becomes a part of the host chromosome (Figure 1(a)). The endpoints of the integrated prophage are marked by two new attachment sites, *attL* and *attR* (for left and right). During excision, *attL* and *attR* undergo a single crossover to regenerate *attB* and *attP*. The proteins that mediate these integration and excision reactions are integrases. Integrases, transposases, resolvases, and invertases are now understood to mediate conservative site-specific recombination, so called because the energy of the phosphodiester bond from the DNA backbone is maintained by a covalent protein-DNA recombination intermediate. In addition, site-specific recombination is not accompanied by overall loss or gain of

DNA. Although being ubiquitous in bacteria, conservative site-specific recombination systems are rare in eukaryotes.

Bacterial mobile genetic elements, such as plasmids, transposons, integrons, and phages, frequently rely on a site-specific recombination system for some aspect of their maintenance or movement. Some elements such as the integrative conjugative elements (ICEs) resemble temperate phage genomes, in that they need to excise from and integrate into the bacterial chromosome, frequently using specific attachment sites (e.g., *attB* and *attP* or *attTn*). Cell-to-cell transfer of ICEs occurs by conjugation of an excised element to a recipient cell, in whose genome the ICE integrates. Integrons are specialized genetic loci for the expression and exchange of gene cassettes, again requiring DNA integration and excision. Superintegrons such as those in *Vibrio* species can contain hundreds of gene cassettes, some of which confer antibiotic resistance and others are implicated in virulence, but majority are of unknown function. The integron platform comprises an integrase gene, *intI*, and a recombination site, *attI*, located just downstream of a promoter. Integrase mediates recombination between the *attI* and an *attC* site located on the incoming circular gene cassette placing the gene cassette so that it is expressed by the promoter. Recombination regenerates the *attI* site, enabling integration of further gene cassettes, and recombination between *attC* sites permits excision.

Resolution systems generally act to split fused genetic elements (co-integrates or tandem repeats) into separate molecules (Figure 1(b)). Typically, the Tn3 family of replicative transposons employs a resolvase to mediate resolution of a co-integrate containing a fusion of the donor and recipient DNA molecules and two copies of the transposon. Resolvase acts on a site within each copy of the transposon to regenerate the donor molecule and to release the recipient, having acquired a complete copy of the transposon. The most general site-specific recombination system in bacterial cells is the XerC/XerD/*dif* system that resolves chromosome dimers formed by homologous recombination during genome duplication, enabling stable chromosome segregation during cell division. Remarkably, the same recombinases, XerC and XerD, are used in bacteria for at least two other purposes: resolution of plasmid multimers to maintain plasmid stability and phage genome integration (e.g., *Vibrio cholera* phage CTX ϕ ; see below).

Inversion systems have evolved in bacteria and their phages to mediate on/off switches of gene expression (phase variation) or to switch between expression of gene coding for functionally

Figure 1 Recombination outcomes. (a) Integration and excision reactions, typically phage or plasmid DNA into and out of the host chromosome. The directionality (i.e., integration vs. excision) of the reaction often depends on the presence of an accessory protein, the recombination directionality factor (RDF). (b) A resolution reaction is usually unidirectional, typically chromosome or plasmid resolution or transposition intermediates. Note that a resolution reaction is essentially the same as excision in panel (a). (c) Inversion switches are usually reversible. In all outcomes the recombination sites are shown as blue or black or blue/black arrowheads. Arrowheads are used to show that the polarity of each site is always maintained after recombination. The different colors do not necessarily mean that the DNA sequences of pairs of recombination sites are different; many reactions use identical recombination sites.

alternative proteins (antigenic variation) (Figure 1(c)). The best-understood inversion system mediates the switching between two antigenic forms of flagella in *Salmonella typhimurium* by Hin invertase. An invertible element contains a promoter that, in one orientation, reads into a gene encoding the H2 flagellin and, in the other, relieves the inhibition on the expression of the gene encoding the H1 flagellin. Although many invertible loci flip the orientation of a promoter, others change the coding sequence itself. In plasmid R64 in *E. coli*, there is a cluster of invertible DNA segments that mediate diversity of the mating pilus, encoded by the *pilV* locus, required for conjugation in liquid cultures. The *pilV* locus consists of a constant 5'-end coding sequence that becomes fused to one of seven possible 3'-end coding sequences. The term coined for this type of complex, and genetically plastic locus is a shufflon. In the opportunistic gut pathogen, *Bacteroides fragilis*, the incidence of invertible systems is taken to a new extreme. There are 23 invertible promoter-containing segments, 4 shufflons, 3 invertible elements containing complete coding sequences, and 30 potential invertases. Many of these switches turn on or off the expression of enzymes for surface polysaccharides or outer membrane proteins, thus changing the antigenicity of the bacterial surface. These switches are stochastic and combinatorial, yielding a highly diverse population of cells on which selection acts. Switching the surface structures of bacteria is a common feature of pathogenic bacteria.

Recombinases and Mechanisms

The minimum requirement for site-specific recombination is a recombinase that recognizes and acts on two recombination sites, which can be identical or of different sequences. The recombinases fall into one of two evolutionary and mechanistically distinct families, the tyrosine and the serine recombinases. In both families, the overall reaction pathway is similar; the recombinase binds to the recombination substrates and

brings them together to form a synapse within which DNA cleavage occurs. Strand exchange then repositions the cleaved DNA ends such that joining of the DNA backbone forms the products.

Tyrosine Recombinases

The tyrosine recombinases include phage, plasmid and integron integrases, resolvases, invertases, and transposases. The eukaryotic type IB topoisomerases also share the chemistry and enzymology of the DNA cleavage–ligation reactions. The tyrosine recombinases have limited primary sequence similarity with most identity in the C-terminal catalytic domain. Sequence comparisons and structural data showed that the proteins contain four strictly conserved amino acids required for catalysis: an arginine–histidine–arginine catalytic triad and the tyrosine nucleophile. Extensive biochemical experiments with phage λ integrase (λ Int) showed that recombination occurs in two stages with one pair of strands exchanged before the second pair. The intermediate in which only one pair of strands has exchanged resembles a Holliday junction (Figure 2).

Biochemical experiments and structural data have yielded a good understanding of the mechanism of the tyrosine recombinases (Figure 2). The simplest examples include the Cre protein from phage P1 and the FLP protein from *Saccharomyces cerevisiae*. Both of these proteins recognize simple recombination sites, *loxP* by Cre and *FRT* by FLP. Each site consists of two binding elements 11–13 bp in length in inverted repeat orientation separated by a 6–8 bp unique sequence where the crossovers occur. Both the N- and C-terminal domains of Cre or FLP interact extensively with the binding element on both faces of the DNA. Binding by Cre monomers to two *loxP* sites is cooperative, and synapse formation is brought about by the formation of a tetramer of subunits with pseudo-fourfold symmetry. The orientation of the DNA in the synapse is antiparallel with respect to the directional sequence

Figure 2 The mechanism of the tyrosine recombinases. (a) Reaction mechanism in Cre-loxP recombination based on insights from Cre/DNA structures. Two loxP sites are blue and black parallel lines, each site containing two binding elements for a Cre subunit. A tetramer of Cre bound to the four binding elements brings the loxP sites together in synapse where the central crossover regions (dotted lines) are reading in opposite directions. The active site tyrosines on two opposing Cre monomers are activated (green) to initiate exchange of two of the four DNA strands to form a Holliday Junction intermediate. Isomerization is a subtle change in DNA conformation in the Holliday junction intermediate that then activates the previously inactive Cre subunits (red) which then initiate exchange of the remaining strands. (b) Structure of the Holliday junction intermediate. The opposing pairs of Cre subunits that are simultaneously active in the tetramer are red and green; the DNA strands are black. The DNA lies almost entirely in one plane. The complex has the N-terminal domains closest to the viewer (PDB entry, 2CRX viewed with Protein Workshop). Reproduced from Van Duyne GD (2001) Crystal structure of the Holliday junction intermediate bound by four Cre subunits. *Annual Review of Biophysics and Biomolecular Structure* 30: 87–104.

at the crossover sequences. Activation of two opposing subunits bound to different substrates cleaves two (so-called ‘top’) strands using the tyrosine nucleophiles, activated by the arginine–histidine–arginine triad that coordinates the scissile phosphate. Acid–base chemistry generates a transient covalent phosphotyrosine linkage to the 3′-end of the cleaved DNA. The free 5′-ends peel off their partner strands and anneal to the unpaired base pairs from the other DNA substrate in a strand swap. The 5′-OH then acts as the nucleophile to attack the phosphotyrosine bond resulting in ligation of the phosphodiester backbone and formation of the Holliday junction. An isomerization reaction occurs that activates the previously inactive pair of opposing recombinase subunits; these cleave the bottom strands and essentially repeat the reactions for the first strand swap, thus completing recombination and

releasing both products and the recombinase. Mechanisms to control the outcome of recombination (i.e., integration versus excision, resolution, and inversion) by the tyrosine recombinases are superimposed on this reaction mechanism (see below).

There are significant variations on the reaction mechanism itself. For most tyrosine recombinases, the identity of the crossover region is essential for efficient recombination, and past and present proposals for the reaction mechanism always ensure that there is a way of reading the identity of this sequence. However, there are some recombinases, notably Tn916 and CTnDOT integrases that do not require extensive DNA identity at the crossover site. These recombinases only need about 2 bp of sequence identity after the position of the first strand cleavage; thereafter, the sequences

Figure 3 XerC and XerD bind to their cognate-binding elements at the *dif* site on chromosome 1 of *V. cholera*, *dif1*, and to the folded *attP* site formed from the CTX ϕ virion DNA. First strand cleavage and rejoining by XerC covalently inserts the ssDNA CTX ϕ genome, and either replication or gap repair then converts this to a dsDNA prophage integrated at *dif1*. The *dif1* site is regenerated in this process, but, at the other end of the prophage, is a *dif*-like site that cannot take part in a reverse reaction and this single integrated phage genome cannot therefore excise. Further integration of CTX ϕ genomes into *dif1* can occur by Xer recombination or into the prophage by homologous recombination; excision occurs between two tandem CTX ϕ genomes by homologous recombination.

at the crossover and second-strand cleavage site can be different. This explains how these transposons can target relatively random sequence.

The integron integrase, IntI, and XerC/XerD can mediate recombination where one of the substrates might be circular single-stranded DNA (ssDNA). In the integron platform, the *attI* site in the chromosome resembles a simple recombination substrate comprised of two recombinase-binding elements flanking the crossover sequence. However, the other recombination substrate, the *attC* site, is generated from a folded circular ssDNA molecule. In *V. cholera*, the host XerC/XerD enzymes and the *dif1* site are exploited for the integration of a single-stranded phage genome, CTX ϕ . The self-pairing in the *attC* sites and the CTX ϕ *attP* sites creates the recombinase-binding elements separated by the crossover sequences (Figure 3). In both cases, the reaction pathway is halted after exchange of only one pair of strands, that is, at the Holliday junction intermediate. DNA replication of the recombination product then yields two different daughter strands, only one of which contains an insertion.

Serine Recombinases

The serine recombinases include phage integrases, resolvases, invertases, and transposases. The resolvase/invertase recombinases are the best understood mechanistically (e.g., $\gamma\delta$ and Tn3 resolvases required for co-integrate resolution, the plasmid resolvase, Sin, and the invertases, e.g., Hin and Gin). The resolvase/invertases are small proteins that contain an approximately 140-amino-acid (aa) N-terminal domain and a small C-terminal domain of 40–50 aa, required for recognition and binding to the recombination substrates. The substrates for the resolvases, the *res* sites, are generally quite large (Tn3 *res* is 114 bp in length) containing three binding sites, called subsites, for three resolvase dimers. Only one of these subsites (i.e., subsite I) is where recombination occurs with the other two being required solely for the control of directionality (see below). Subsite I is an inverted repeat about 28 bp in length. The substrates for the invertases are also inverted repeats; the *hixL* and *hixR* sites recognized by Hin invertase are 26 bp in length. Both Hin and Gin require an accessory protein, Fis, bound to an enhancer sequence to control recombination.

The mechanism of the resolvase/invertases is described here by considering only the events at the recombination sites (Figure 4). The serine recombinase N-terminal domain is required for catalysis, strand exchange, and subunit–subunit interactions. In solution serine recombinases are dimers, mediated through a dimer interface in the catalytic domain. Recombinase dimers bind to their recombination substrates, and further protein–protein interactions, also mediated through the N-terminal domains, generate a tetramer of recombinase subunits and bring the two DNA substrates together in a synaptic complex. Large conformation changes occur within the synaptic tetramers that are presumed to activate catalysis. The active site serine residues on each of the four recombinase subunits attack the scissile phosphates on all four DNA strands, transferring the 5'-phosphates to the serine hydroxyl. The DNA cleavage leaves a 2-bp staggered break with a free 3'-OH and the covalent phosphoserine linkage to the recessed 5'-end. A pair of recombinase subunits bound to different DNA substrates then rotates 180° relative to the other pair to align the DNA ends, such that ligation of products occurs through the attack by the free 3'-OH groups on the phosphoserine bonds. As cleavage occurs in all four DNA strands at the same time, only the subunit–subunit interactions hold the DNA together. A crystal structure of a tetrameric covalent intermediate of $\gamma\delta$ resolvase reveals a large flat hydrophobic interface within the tetramer that would enable subunit rotation without dissociation.

Other members of the serine recombinase family have different domain structures. The large serine recombinases have the N-terminal catalytic domain but have a large 300–500-aa C-terminal domain. The large serine recombinases include phage-encoded serine integrases that, like λ Int, use an *attP* and *attB* site to integrate phage DNA. The integrases from the *Streptomyces* phage ϕ C31 and from a mycobacteriophage Bxb1 are the most studied of this group. The ϕ C31 and Bxb1 integrases have a similar mechanism of strand cleavage and strand exchange to the resolvase/invertases. The large C-terminal domains are required for substrate recognition

Figure 4 Mechanism of a serine recombinase. (a) The reaction mechanism at the recombination sites for the resolvase/invertases and for serine integrases. Serine recombinases bind to a pair of recombination sites (shown here as two parallel black or gray lines with the 2-bp crossover sequences shown as two short vertical lines) as dimers (two red and two blue subunits) and then form a tetramer, bringing the DNA sites together in a synapse. All four subunits are simultaneously activated to cleave the DNA, forming in each subunit a phosphoserine link to a recessed 5'-end and leaving a free 2-bp 3'-overhang. Subunit rotation exchanges two DNA half sites, repositioning the half sites into a recombinant format. Ligation of the DNA backbone generates the recombinant molecules. Note that base pairing must occur between the 3'-overhangs and the recessed 5'-ends in the recombinants; mismatches in the recombinants lead to reformation of the substrates trapping knots or catenanes in the process. If the 2-bp sequence at the crossover is nonpalindromic, then only one of two synapse structures that differ by the relative orientations of the recombination sites will avoid mismatches in the recombinants. (b) The tetrameric covalent intermediate of an activated mutant of $\gamma\delta$ resolvase (PDB 1ZR4, viewed with Protein Workshop). The $\gamma\delta$ subunits colored red and blue represent the dimers that initially bound either a black or gray recombination site, respectively. The structure is arbitrarily shown just after cleavage and prior to strand exchange (two black half sites and two gray half sites are still adjacent to each other in a parental format). The large flat interface that mediates subunit rotation is easily visible down the center of the tetramer. (a) Reproduced from Stark WM, Boocock MR, and Sherratt DJ (1992) Catalysis by site-specific recombinases. *Trends in Genetics* 8(12): 432–439.

and for directional control (see below). There is also a group of uncharacterized transposases (e.g., IS607) that have the serine recombinase catalytic domain at the C-terminus and a small DNA-binding domain at the N-terminus.

Control of Recombination

Maintaining Site Polarity

An important feature of site-specific recombination systems is the need to maintain the integrity of the recombination sites through repeated rounds of recombination. To this end, all recombination systems have a mechanism to distinguish the polarity of the substrates such that the left side of one recombination site always joins to the right side of the other and vice

versa. This strict requirement for left–right joining also ensures a predictable outcome for recombination. For example, in the simple systems such as Cre-*loxP* and FLP-FRT, the recombination sites have the directional crossover sequence that defines polarity. Cre recombines two *loxP* sites in head-to-tail configuration on a plasmid to produce two separate plasmid circles (resolution products), but if the *loxP* sites are fully symmetrical (*loxS*) both resolution and inversion occur. Many serine recombinases also rely on the crossover site to define polarity as base pairing at the 2-bp staggered break is important for ligation of the recombinants. As for the *loxS* site, if the 2-bp crossover sequences are made symmetrical in both recombination substrates, normal left side to right side joining is lost. Thus far, all serine integrases and invertases have nonsymmetrical 2-bp crossover sites to avoid loss of substrate polarity.

Figure 5 Two common mechanisms of control of recombinases. (a) The topological filter as displayed by $\gamma\delta$ and Tn3 resolvases. Dimers of resolvase bind to the three subsites in the transposon *res* sites that lie at the boundaries of the two elements to be resolved (illustrated by thick and a thin lines within the co-integrate). Subunit interactions between resolvases bound at sites II and III trap three negative nodes and bring the resolvases bound at site I together to form an active tetramer. Subunit rotation is right handed, driven by stored energy from supercoiling. The products are almost entirely singly linked catenanes that are resolved by the bacterial topoisomerase IV. (b) Control of integration vs. excision by λ Int: (i) arrangement of Int and accessory protein-binding sites on the attachment sites. *attP* is the blue line comprising the arms (dashed) and the core (solid) and *attB* is black. *attL* and *attR* comprise a half site from *attP* (blue) and a half site from *attB* (black). λ Int binds to arm sites (small blue arrowheads) and core sites (longer blue and black arrowheads). The *attP* site also has binding sites for IHF (white rectangles) and for Xis (white arrows). (ii) λ Int integration and excision is controlled by the formation of two different synapse structures depending on the presence of different DNA bending proteins (shown as white circles) and the nature of the substrates. At the center of both synaptic complexes is a tetramer of Int subunits contacting arm and core sites simultaneously. Each int subunit is shown in a different color, with the large oval being the core-binding and catalytic (CB) domains and the smaller oval is the N-terminal, arm-binding domain. Only once the synapse is formed are the CB domains activated to initiate strand exchange using the mechanism described for the tyrosine recombinases (Figure 2). (a) Adapted from Grindley ND, Whiteson KL, and Rice PA (2006) Mechanisms of site-specific recombination. *Annual Review of Biochemistry* 75: 567–605. (b) Reproduced from Van Duyne GD (2005) Lambda integrase: Armed for recombination. *Current Biology* 15(17): R658–660, with permission from Elsevier.

Controlling the Outcome

Site-specific recombinases have the capacity to cleave DNA, an activity that, if it goes uncontrolled, could lead to many unwanted DNA rearrangements or potentially lethal double-strand breaks. All site-specific recombinases are therefore inactive until the correct protein–protein and protein–DNA interactions are made in a synaptic complex containing both substrates and the recombinases. Cre and FLP are unusual systems as they are reversible (although with Cre-*loxP* resolution is greatly favored over integration solely due to kinetic factors). Most recombination systems have accessory proteins and/or accessory binding sites to control the directionality or outcome of a recombination reaction.

Many resolvases of the serine recombinase family such as Tn3 and $\gamma\delta$ resolvases have accessory resolvase-binding sites close to

the recombination site that wrap the DNA to form a nucleoprotein complex with a specific topology (Figure 5(a)). Only when the two *res* sites are in the same DNA molecule and in a head-to-tail orientation is the synapse formed that activates catalysis and recombination. This topological filter ensures that recombination cannot occur between two recombination sites in head-to-head orientation on the same molecule or between sites on different molecules. The substrates for recombination by Sin recombinase have an accessory-binding site for a Sin dimer that directly contacts Sin bound at the recombination site and one binding site for a histone-like protein whose function is to help bend the DNA into the correct synapse. This arrangement of binding sites also acts as a topological filter.

Invertases such as Hin and Gin also use topological filters to ensure inversion rather than resolution and to prevent integration. With the Hin system a recombination enhancer segment

binds two Fis dimers that contact Hin dimers bound to *hixL* and *hixR*. The enhancer must be located on the same molecule as the invertible segment and up to about 4 kbp from the nearest *hix* site. In addition, the DNA in this synaptic complex (or invertosome) follows a specific topological path ensuring that only sites on the same molecule and in inverted orientation can recombine.

The bacterial-encoded tyrosine recombinases, XerC and XerD, are the most versatile of all the recombinases being required for chromosome dimer resolution, plasmid resolution, and integration of some phage genomes. Each different function requires a different set of accessory proteins and pairs of recombination sites. XerC and XerD bind to their cognate-binding elements on either side of the crossover sequence (e.g., [Figure 3](#)). In the resolution of chromosome, dimers XerC and XerD bind to two identical *dif* sites, which are the recombination substrates located in the *ter* region of the chromosome. The recombinases are activated by FtsK, a protein located in the closing cell division septum and that pulls the DNA toward the XerC/XerD/*dif* complex. FtsK activates the XerD pair to make the first crossover followed by XerC activation and the second crossover. In plasmid resolution, the recombination sites, *cer*, have slightly different sequences from *dif* such that any strand cleavage is inhibited until two accessory proteins, PepA and ArgR, bind generating a topologically defined complex similar to that made by the $\gamma\delta$, Tn3, and Sin resolvases. In phage integration, XerC and XerD are again required, this time without needing an accessory protein but using a folded ssDNA *attP* site (see above and [Figure 3](#)).

Phage integrases such as λ Int have an elaborate mechanism for controlling integration and excision of the phage genome involving different juxtapositions of DNA-binding sites for both integrase and accessory proteins. λ Int is a tyrosine recombinase and has the core-binding and catalytic domain analogous to Cre and Xer recombinases but has, in addition, a small N-terminal domain, the arm-binding domain. This domain binds to specific arm sequences in the *attP* site, which is about 240 bp in length ([Figure 5\(b\)\(i\)](#)). Thus, the heterobivalent DNA-binding activity of λ Int contacts both the core site where the crossover occurs, and the arm-binding sites simultaneously. These contacts are facilitated by a host protein, integration host factor (IHF), a bending protein that binds to its cognate-binding sites in *attP*. In integration, binding to *attP* by Int and IHF forms a nucleoprotein structure (the intasome) that then captures the small *attB* site consisting only of a core site to form the integration synapse ([Figure 5\(b\)\(ii\)](#)). Recombination occurs within this tetramer to yield *attL* and *attR*. Recombination between *attL* and *attR* (excision) requires another protein, Xis, encoded by the phage genome and which binds to *xis*-binding sites in the *attP* derived half of *attR*. In the presence of λ Int, Xis, IHF, and, under some circumstances, Fis, an excision synapse is assembled that activates *attL* $\times$ *attR* recombination ([Figure 5\(b\)\(ii\)](#)).

The phage-encoded serine integrases such as Bxb1 and ϕ C31 integrases have evolved a much simpler system for the regulation of directionality. Only *attP* $\times$ *attB* recombination occurs with integrase alone, and like λ Int an accessory protein (Xis or recombination directionality factor (RDF)) is required for *attL* $\times$ *attR* recombination. Unlike λ Int system, the recombination sites are both relatively short (<50 bp) and are

different sequences. No other proteins are required other than integrase and the RDF. The mechanism of directionality relies on different DNA-induced recombinase conformations that enable synapsis and activation of catalysis. The default reaction for the serine integrases is integration, and the recombination substrates *attP* and *attB* are both imperfect inverted repeats. The products *attL* and *attR* contain half sites from *attP* and *attB*, and the integrase subunits bound to these half sites have different conformations that prevent the excision reaction. The role of the RDF identified from the mycobacteriophage Bxb1 is to bind directly to integrase, preventing the *attP* $\times$ *attB* reaction but stimulating the *attL* $\times$ *attR* reaction.

Conclusions and Applications

Bacteria use conservative site-specific recombination systems for a wide variety of processes that are profoundly linked to both the stability of genomes and their evolution. Mechanistic studies on the two distinct protein families that mediate site-specific recombination reactions have revealed precedents in protein function and DNA recognition. Because some recombination systems are simple requiring only the recombinase and the two recombination sites, many are being exploited as tools for manipulation of very complex genomes and potentially as vectors for gene therapy in humans and animals. Optimization of the recombinases in synthetic biology applications depends on a detailed understanding of their mechanism and regulation.

Glossary

Chemotaxis Directed movement of cells toward (or away from) the source of diffusible chemoattractant (or repellent) molecules.

G protein Heterotrimeric proteins with inactive (guanosine diphosphate (GDP)-bound) and active (guanosine triphosphate (GTP)-bound) states which are activated by ligand-occupied receptors and, in turn, activate downstream targets within the cell.

G-protein-coupled receptors Cell surface, integral membrane proteins possessing seven membrane-spanning α -helices and usually capable of activating cytosolic G proteins upon binding specific extracellular signaling molecules (also known as seven-transmembrane or serpentine receptors).

Signal transduction Molecular events by which the perception of an extracellular signal by a cell is translated into an appropriate cellular response.

Dictyostelium Development and Cyclic Adenosine Monophosphate Signaling

Dictyostelium discoideum is an amoeba found in soil where it feeds on bacteria. In order to survive periods of starvation, 10^4 – 10^5 amoebae aggregate and execute a 24-h developmental program that yields a fruiting body comprised of a round mass of spores held aloft by a slender stalk (Figure 1(a)). When nutrients return to the environment, spores germinate to yield amoebae which resume cell division.

Not long after Sutherland and his colleagues discovered cyclic adenosine monophosphate (cAMP) to be an important intracellular second messenger in hormonal signaling, Konijn and his associates demonstrated that cAMP is a potent chemoattractant for *Dictyostelium* and correctly speculated that it was the so-called acrasin secreted by starving amoebae which mediates their aggregation. Shaffer had proposed that the acrasin would be emitted periodically by cells at aggregation centers and relayed outwardly as waves by surrounding cells. Indeed, exogenous cAMP was shown to elicit the transient activation of adenyl cyclase and secretion of cAMP. Tomchik and Devreotes later demonstrated the concentric waves of extracellular cAMP waves which arise every ~6 min at aggregation centers and travel radially outward through aggregating populations. Subsequent pharmacologic characterization of these responses established the framework for the identification of the cAMP receptors.

Identification and Properties of cAMP Receptors

The molecular identification of the first cAMP receptor, cAR1, began with its photoaffinity labeling with the cAMP analog, 8-azido-[32 P]cAMP. This approach identified a protein of either 40 or 43 kDa depending on whether or not the cells had been exposed to cAMP, suggesting the existence of a reversible, ligand-induced modification which proved to be phosphorylation. Radiolabeling of cells with [32 P]phosphate permitted purification of the 43-kDa phosphorylated form of the receptor.

Antibodies directed against purified cAR1 led to the isolation of a complementary DNA (cDNA) that encoded a protein of the expected size and hybridized to a messenger RNA (mRNA) expressed transiently in early development consistent with cAMP binding. Formal proof that the isolated cDNA did indeed encode cAR1 came from expression of the cDNA, which resulted in increased cAMP binding, and disruption of the corresponding gene, which obviated cAMP binding and cAR1-mediated responses. The deduced sequence of cAR1 possessed seven putative transmembrane domains (Figure 2) and exhibited weak homology to mammalian G-protein-coupled receptors (GPCRs). cAMP stimulation of guanosine triphosphate (GTP) binding to isolated membranes and GTP hydrolysis was further evidence that cAR1 is indeed coupled to a G protein. This together with studies of yeast pheromone signaling provided the earliest indications that virtually all eukaryotes have inherited these ancient sensory mechanisms.

Three other highly homologous cAMP receptors, designated cAR2–4, were subsequently identified by hybridization with a cAR1 probe. The cARs are expressed successively during development, peaking in expression at roughly 5-h intervals in the order: cAR1, cAR3, cAR2, and cAR4 (Figure 1(b)). Disruption of the genes encoding each cAR results in developmental defects consistent with the timing of their expression. cAR1[−] cells fail to aggregate. cAR2[−] cells arrest shortly after aggregating at the mound stage. cAR3 gene disruption has been variously reported either to have no apparent effect or to interfere with spore cell differentiation late in the mound stage and consequently yield fruiting bodies predominantly comprised of stalk cells. cAR4[−] cells develop normally beyond the mound stage but exhibit defects in culmination, resulting in misshapen fruiting bodies.

The cARs differ markedly in their affinities for cAMP. The early cARs, cAR1 and cAR3, have high affinities (i.e., low- to mid-nM K_d 's), whereas those expressed later in development, cAR2 and cAR4, have low affinities (K_d 's > 1 μ M). These affinities are appropriate for the extracellular cAMP concentrations that exist at these stages of development (Figure 1(c)). During aggregation, the cAMP signal oscillates from sub-nM to near μ M

Figure 1 Correlation of developmental morphology, cAR expression, and extracellular cAMP levels. See text for additional details.

Figure 2 Model of cAR1. Dark blue spheres represent amino acids conserved in all four cARs. Densely packed amino acids in the plane of the membrane (gray bar) signify the seven hydrophobic transmembrane helices. Nonconserved amino acids (light gray spheres) in the region labeled major affinity determinant are largely responsible for the widely differing cAMP affinities of cAR1 and cAR2 (and possibly other cARs). Clusters of serines in the C-terminal cytoplasmic domain (S), the distribution of ligand-induced phosphorylation (P), and the putative disulfide bridge (—S—S—) are also indicated. cAR2–4 differ in the lengths and sequences of their C-terminal cytoplasmic domains.

concentrations. By contrast, external cAMP oscillates at elevated concentrations exceeding $1\text{ }\mu\text{M}$ in the multicellular stages. Nonconserved residues in the second extracellular loop largely determine whether a cAR has a high or low affinity (Figure 2). By analogy with rhodopsin, this extracellular loop, positioned by disulfide linkage to the extracellular end of the third transmembrane helix, is likely to lie at the entrance to the cAMP-binding cleft of cARs and, thereby, influence binding.

Signaling Pathways

cAR1 is perhaps the most versatile GPCR yet to be characterized as it regulates a wide range of downstream effectors and biological responses. Consequently, it serves as a valuable model for understanding diverse modes of GPCR signaling. cAR1 mediates three principal cellular responses during aggregation: (1) propagation of cAMP waves, (2) chemotaxis up the cAMP gradient of each oncoming wave, and (3) regulation of genes required for development. The pathways underlying these responses have been determined to a large extent (Figure 3(a)). Most striking is the dichotomy between signaling pathways that involve G proteins and those that do not. Comparatively less is known about the pathways governed by cAR2–4 in large measure due to technical challenges posed by multicellularity, although significant progress has been made toward elucidating mechanisms by which these cARs promote cell differentiation in multicellular stages.

G-Protein-Dependent Pathways

Dictyostelium possesses at least nine heterotrimeric G proteins comprised of distinct α subunits (designated $G\alpha 1$ – 9) and common β and γ subunits. Genetic and biochemical evidence indicate that $G\alpha 2\beta\gamma$ is the principal G protein to which cAR1 couples. Activation of $G\alpha 2\beta\gamma$ by cAR1 liberates the $G\beta\gamma$ dimer and GTP-bound $G\alpha 2$, which, in turn, activate various effectors.

The activated G protein triggers a network of interconnected pathways that ultimately control cell–cell signaling and chemotaxis. The $G\beta\gamma$ dimer-mediated activation of phosphoinositide-3-kinase (PI3K) converts the membrane phospholipid PIP_2 (phosphatidylinositol-4,5-bisphosphate) into PIP_3 (phosphatidylinositol-3,4,5-trisphosphate). PIP_3 , in turn, binds to the PH domain of cytosolic regulator of adenylyl cyclase (CRAC), thus recruiting it to the plasma membrane. CRAC participates in the activation of adenylyl cyclase A (ACA) by an unknown mechanism. The resulting cAMP functions intracellularly via

Figure 3 cAMP receptor signaling pathways. Pointed (↓) and flatheaded (⊥) arrows indicate activation and inhibition, respectively. (a) cAR1 pathways leading to chemotaxis, cAMP relay, and gene regulation. G-protein-independent and nonadapting pathways are indicated. In multicellular stages, cAR2–4 might activate some of the pathways shown for cAR1. (b) Role of cARs in the GskA-mediated determination of cell fate. cAR2 (not shown) might promote prestalk cell differentiation at the mound stage in the manner shown for cAR4.

protein kinase A (PKA) to modulate gene expression and, in addition, is secreted from the cell in order to relay the cAMP signal to neighboring cells.

The receptor–G protein system leads to the activation of two protein kinase B (PKB) isoforms that are critical for chemotaxis. Protein kinase B type A (PKBA) is a PH domain-containing protein that depends on PIP₃ for its activation. In addition, protein kinase B-related 1 (PKBR1) is myristoylated and activated independently of PIP₃. Both PKBs are regulated by target of rapamycin complex 2 (TorC2) via phosphorylation of their hydrophobic motifs. In cells undergoing chemotaxis in a shallow cAMP gradient, these PKBs are exclusively activated at the cells' leading edge where they presumably promote actin assembly and pseudopod extension. These mechanistic insights into cAR1-mediated chemotaxis, namely the involvement of PI3K activation and recruitment of PKB to the leading edge, have since been found to also pertain to the chemotaxis of a variety of mammalian cells including neutrophils.

The Gα2 subunit is implicated in the cAR1-dependent activation of guanylyl cyclase which provides another important input to the chemotaxis machinery. The product of guanylyl cyclase, cGMP, regulates myosin heavy chain kinases and, thereby, promotes the assembly of conventional myosin II in posterior and lateral regions of chemotaxing cells where it can propel the rear of the cell forward upon contraction and suppress lateral pseudopod formation.

G-Protein-Independent Pathways

Several cAR-mediated responses appear to be G-protein-independent based on their preservation in cells lacking what is believed to be the sole G-protein β-subunit gene. These include phosphorylation of cAR1, uptake of Ca²⁺, and activation of the mitogen-activated protein kinase Erk2, the transcriptional regulators G-box-binding factor (GBF) and signal transducer and activator of transcription (STAT), and the glycogen synthase kinase-3 (GSK3) homolog GskA.

cAR1 is phosphorylated on serine residues within its C-terminal cytoplasmic domain. The 18 serines in this domain exist in four clusters (Figure 2). In unstimulated cells, cAR1 is basally phosphorylated within clusters 2 and 3. Upon stimulation with cAMP, cAR1 becomes reversibly hyperphosphorylated due to the addition of approximately two phosphates within cluster 1 and a third phosphate within cluster 2. Cluster 1 phosphorylation causes the 40- to 43-kDa electrophoretic shift. Other cARs also undergo cAMP-induced phosphorylation commensurate with their affinities.

Erk2 promotes the intracellular accumulation of cAMP by negatively regulating RegA, a cAMP-specific phosphodiesterase. Erk2 is presumably the third of three kinases in a typical mitogen-activated protein (MAP) kinase cascade. The identity of the upstream kinases as well as the G-protein-independent mechanism by which cAR1 activates the cascade remains to be determined.

cAMP triggers the rapid and transient influx of Ca²⁺ ions in aggregation-competent cells. This is mediated largely by cAR1 due to its natural abundance at this stage in development. However, expression of cARs in vegetative cells indicates that the components required for uptake are expressed at this stage and that other cARs can also mediate Ca²⁺ uptake. The magnitude of Ca²⁺ uptake is roughly proportional to receptor level, indicating that cARs are the limiting component for this response.

GBF binds G-rich elements in early post-aggregative genes and is required for their induction by cAMP. Gene disruptions suggest that either cAR1 or cAR3 mediate the G-protein-independent activation of GBF. In contrast to many aggregation-stage genes whose expression requires periodic cAMP pulses that mimic natural cAMP waves, GBF-mediated gene expression is induced by constant cAMP, indicating that it is not subject to adaptation. Thus, the GBF pathway is appropriately activated upon aggregation when extracellular cAMP rises to levels that persistently occupy cAR1.

STAT proteins have been extensively studied in the context of cytokine signaling in mammalian immune cells. In *Dictyostelium*,

exogenous cAMP triggers STaT's phosphorylation on tyrosine, SH2 domain-mediated dimerization, and translocation to the nucleus where it governs prestalk gene expression. cAR1 is required for this response but it can be substituted in this capacity with cAR2, suggesting that multiple cARs might activate STaT during development. The cAR-activated tyrosine kinase involved remains to be identified.

GskA, a homolog of GSK3, is an important regulator of cell fate in *Dictyostelium* and cARs play key roles in regulating its activity. GskA activity promotes spore cell differentiation, whereas inactivity results in stalk cell differentiation (Figure 3 (b)). Independent of G proteins, cAR3 activates the nonreceptor tyrosine kinase Zak1 which, in turn, phosphorylates and activates GskA. On the other hand, cAR4 (and perhaps cAR2) activates a phosphotyrosine phosphatase, resulting in the dephosphorylation and inactivation of GskA. The role of G proteins in the latter process, if any, is not known. Therefore, cAR3 signaling promotes spore differentiation and cAR2 and cAR4 favor stalk cell differentiation. Because cAR2 and cAR4 are expressed predominantly in prestalk cells, it is unclear whether these mechanisms determine cell fate or act thereafter in cell-type maintenance.

One known target of cAMP-activated GskA is STaT. GskA phosphorylates multiple serines of STaT, causing it to be exported from the nucleus. This is one mechanism by which cAR3 signaling might oppose prestalk differentiation. As has been described for other developmental systems, GskA may also determine cell fate by phosphorylating β -catenin and thus targeting this transcriptional co-activator for destruction.

Mechanisms of G-Protein-Independent Signaling

It remains to be determined how cAMP-occupied cAR1 communicates with and activates these effectors. By analogy with G proteins and also mammalian G-protein-coupled receptor kinases (GRKs), the yet to be identified cAR kinase might interact selectively with the ligand-occupied conformation of the receptor's cytoplasmic loops. Other G-protein-independent processes such as Ca^{2+} uptake could involve lateral signal transduction within the plane of the membrane by direct interaction of cAR1 with another integral membrane protein, analogous to the interaction of *Halobacterium* sensory rhodopsins (SI and SRII) with their associated histidine kinases (HtrI and HtrII).

Desensitization Mechanisms

In general, receptor-mediated responses are governed by various desensitization mechanisms which attenuate the cell's responsiveness. cAMP triggers the sequential phosphorylation ($t_{1/2} \sim 2$ min) and internalization ($t_{1/2} \sim 15$ min) of cAR1. cAR1 phosphorylation causes a several-fold reduction in the receptor's intrinsic affinity for cAMP, which may extend the range of cAMP concentrations to which the receptor can respond during aggregation. In addition, preliminary results indicate that phosphorylation of cAR1 is a prerequisite for its internalization as in other systems. Prolonged cAMP exposure results in downregulation of cAR1 levels, the combined effect of diminished cAR1 gene transcription and cAR1 degradation. Degradation presumably results from delivery of internalized receptors to lysosomes.

On a more rapid timescale, nearly all of the cAR1-mediated responses to abrupt cAMP increases are transient, returning to prestimulus levels in 30 s to several minutes despite constant stimulation. This rapid and reversible attenuation of responses is referred to as 'adaptation'. The few responses that do not adapt include cAR1 phosphorylation and GBF activation. The mechanisms of adaptation are poorly understood and might be distinct for each pathway. cAR1 phosphorylation appears not to be involved as elimination of phosphorylated serine residues in cAR1 by site-directed mutagenesis has little impact on the kinetics of these responses. Cells adapted to one cAMP concentration can respond to yet higher concentrations (provided the receptor is not saturated). This observation indicates that adaptation is a graded signal that is just sufficient to offset the excitatory signal, the strength of which also reflects receptor occupancy.

Studies suggest that adaptation occurs downstream of G protein activation. The activation of the G protein can be monitored by observing the loss of fluorescence resonance energy transfer (FRET) occurring between coexpressed G α -CFP and G β -YFP subunits. These FRET experiments have shown that the G protein is persistently dissociated in adapted cells. Yet, most downstream events including PIP₃ production and PKB, TorC2, and ACA activation adapt. Taken together, these findings suggest that an adaptation pathway emanates from cAR1 and acts upon the excitatory pathway somewhere beyond the G protein.

Gradient Sensing in Chemotaxis

Temporal challenges with fixed cAMP concentrations as described above have been invaluable for deciphering cAR-mediated pathways and revealing the existence of adaptation mechanisms. However, natural cAMP waves also contain spatial information which the cells must rapidly and accurately sense for efficient chemotaxis. Although cAR1 is uniformly distributed in the plasma membrane, shallow cAMP gradients differing by as little as 2% across the length of the cell prompt highly asymmetric localization of various proteins, indicating that the cell senses and amplifies small differences in cAR1 occupancy on this surface. Proteins with PH domains including PKB and CRAC are highly localized to the plasma membrane of the cell's leading (or anterior) edge, indicative of elevated PIP₃ levels. This reflects the recruitment of PI3K to the anterior plasma membrane and its subsequent activation. The membrane translocation of PI3K is mediated by its N-terminal domain which presumably binds an entity in the plasma membrane that is generated in response to cAR1 activation. Conversely, phosphatase and tensin homolog (PTEN) is associated with the posterior plasma membrane via specific interactions with PIP₂. Thus, PTEN is excluded from the anterior membrane where PI3K actively converts PIP₂ to PIP₃ and instead localizes to posterior regions where PIP₂ should be more abundant. Localization of the antagonistic activities of PI3K and PTEN to opposing poles of the cell should result in a steep gradient of PIP₃ and associated PH domain-containing proteins. Other pathways regulated by cAR1 are also polarized in chemotaxing cells. For example, phosphorylated PKBR1 is found selectively at the cell's leading edge. Precisely how the

cell amplifies the directional information of a shallow chemoattractant gradient to achieve extreme gradients of activities within the cell is likely to be critically important for efficient chemotaxis and is under intensive investigation.

Glossary

Allosteric binding Binding of ligands to regulatory sites within a protein.

Autoinhibition Effect of one region of an enzyme to block the action of the catalytic site of another region of that same enzyme.

CAP-related domains Cyclic nucleotide (cN)-binding domains containing ~110 amino acids that provide for cN binding in PKA, PKG, guanine-nucleotide exchange factor (GEFs), and cN-gated cation channels and are evolutionarily related to the bacterial catabolite-gene activator protein.

Chimeric proteins Proteins that are composed of multiple subdomains each of which provides for a specific function of that protein.

Dual specificity Proteins that are not entirely selective among closely related ligands, for example, cAMP and cGMP.

GAF domains Domains of ~120 amino acids that provide for binding of a variety of ligands and protein–protein interactions in diverse proteins.

Phosphohydrolase Enzyme that breaks a phospho-ester bond.

Introduction

Cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP) are prominent second-messenger molecules (Figure 1) that are synthesized by guanylyl cyclases (GCs) and adenylyl cyclases (ACs), respectively. The balance between the activities of the cyclases and phosphodiesterases (PDEs) determines cellular cyclic nucleotide (cN) levels (see cGMP-signaling pathway; Figure 2). Although cNs can be exported from cells by certain members of the multidrug transport proteins or exit via gap junctions, rapid lowering of cNs by action of PDEs is quantitatively the most important process. The cyclic phosphate ring of cGMP and cAMP is a key feature by which PDEs recognize their substrates, and it is highly resistant to most other phosphohydrolases. Nucleotides such as guanosine diphosphate (GDP), 5'-GMP, adenosine diphosphate (ADP), or 5'-AMP that lack this ring do not significantly interact with the catalytic sites of PDEs even at high concentrations. Structural features of the purine (Figure 1) also provide critical features for interaction of the cN substrates with PDEs. In the catalytic sites of cGMP-specific PDEs, a hydrogen bond between an invariant glutamine and the oxygen at the C6 position of the guanine is extremely important as is hydrophobic stacking between a conserved phenylalanine and the heterocyclic ring of guanine. Potent and specific inhibitors also utilize these contacts as well as novel contacts within and near the catalytic pocket.

Distribution of cAMP and cGMP

cAMP is apparently present in all eukaryotes, but cGMP is less widespread (Figure 1). The yeast genome lacks identifiable sequences for GCs or known cGMP-binding domains. However, *Dictyostelium*, *Paramecium*, *Tetrahymena*, *Trypanosomes*, and *Plasmodium* contain GCs. The role of cGMP in most of these organisms is not understood, but in *Dictyostelium* cGMP participates importantly in chemotaxis and osmoregulation. In mammals, cGMP-signaling pathways are prominent in many

processes including smooth muscle proliferation and contraction/relaxation, visual transduction, platelet disaggregation, neuronal viability, bone growth, apoptosis, water and electrolyte homeostasis, memory and learning, cardiac functions, and aldosterone synthesis.

Classification of PDEs

Two evolutionarily distinct classes of PDEs, class I and class II, have been identified; to date, both class I and class II PDEs occur in some genera, for example, *Dictyostelium* and *Saccharomyces*. Class I PDEs are found in both protozoans and metazoans, but all known mammalian PDEs are class I PDEs. In eukaryotes, the catalytic sites and allosteric cN-binding sites in class I PDEs are functionally and evolutionarily distinguished from each other and from those of other known intracellular cN receptors; these include cN-binding sites in proteins such as the cAMP- and cGMP-dependent protein kinases (PKA and PKG, respectively) that belong to the bacterial catabolite gene-activator protein (CAP-related family), the cGMP-binding domains in some PDEs, and anion transporters. However, class II PDEs contain an evolutionarily distinct catalytic domain, and allosteric cN-binding sites in these proteins belong to the CAP-related family of proteins.

Class I PDEs

The class I PDE superfamily in mammals contains 11 PDE families (PDEs 1–11) that are products of 21 separate genes. Classification is based on the order of discovery, extent of similarity in the amino acid sequences, substrate specificities, regulatory features, and DNA sequences. Based on *in vitro* determinations of substrate preferences, three are cAMP-specific PDEs (PDEs 4, 7, and 8), three are cGMP-specific PDEs (PDEs 5, 6, and 9), and five are dual-specificity PDEs (PDEs 1, 2, 3, 10, and 11) (Figure 3). In the latter group, the relative affinities and catalytic rates for cGMP and cAMP breakdown and the affinities

Guanosine 3', 5'-monophosphate (cyclic GMP) Adenosine 3', 5'-monophosphate (cyclic AMP)

Figure 1 Molecular structures of cGMP and cAMP. The structures of cGMP and cAMP differ only at the N-1, C-6, and C-2 positions, but these differences provide for specific and selective interaction with phosphodiesterase catalytic sites. The *syn* conformation of both nucleotides is shown.

Figure 2 Model of cGMP signaling in cells. Intracellular levels of cGMP are determined by the relative activities of guanylyl cyclases and phosphodiesterases. There are two families of guanylyl cyclases; form that is largely cytosolic is activated by nitric oxide and a membrane-bound form is activated by natriuretic peptides and guanylylins. cGMP breakdown is catalyzed by the catalytic sites of phosphodiesterases that are either cGMP-specific or PDEs that hydrolyze both cGMP and cAMP, that is, dual-specificity PDEs. cGMP also interacts with allosteric cGMP-binding sites on cGMP-dependent protein kinase (PKG), cGMP-gated cation channels, and cGMP-binding phosphodiesterases to bring about its physiological effects.

for certain inhibitors can vary significantly among members of a single family as exemplified by PDE1 isoenzymes.

Domain Structure

Each class I PDE monomer is a chimeric protein that includes a conserved catalytic domain (C domain) of ~270 amino acids that is located more C-terminal to its regulatory domain (R domain). Among all known class I PDEs, only 14 amino acids are invariant, and most of these are located in the catalytic pocket. These most likely provide for critical structural and

Figure 3 Schematic depiction of structural features of mammalian class I cGMP-hydrolyzing phosphodiesterases (PDEs). Arrangements of the regulatory (R) domains and catalytic (C) domains are shown for a monomer, although most known mammalian phosphodiesterases exist as dimers or oligomers. Known sites of phosphorylation (P) are indicated. The highly selective allosteric cGMP-binding is associated with GAF-A domains in PDEs 5 and 11 and with GAF-B in PDE2. All isoenzymes of the PDE2, PDE5, and PDE6 families contain two GAF domains. GAF-B in PDE10 binds cAMP with high affinity and selectivity. The role(s) of GAF domains in PDEs 10 and 11 are not known; splice variants within the PDE11 family contain 1, 2, or no complete GAF domains. The open block in PDE3 is a novel 44 amino acid insert in the catalytic domain of this family. Cross-hatched boxes denote calmodulin-binding domains (1 or 2) in the R domain of PDE1.

catalytic features. The R domains of PDEs, which are structurally and functionally more diverse, confer distinct regulatory features for each PDE family (Figure 3). The R domains contain varied subdomains including phosphorylation sites, autoinhibitory sequences, subcellular localization signals, dimerization motifs, and GAFs; GAFs are ancient domains of ~120 amino acids that occur in five PDE families. The name is derived from recognition of this motif in diverse proteins (cGMP-binding PDEs, *Anabaena* AC, and *Escherichia coli* FhlA transcription factor). Depending on the PDE in which they are located, GAFs can contribute to dimerization, interaction with other proteins, or interaction with ligands such as cGMP or cAMP. Cyclic GMP has high affinity and strong selectivity for GAFs in PDEs 5, 6, and 11, but cAMP interacts weakly with these sites in PDE2. GAFs in PDE10 have high affinity and selectivity for cAMP.

Catalytic Domains

X-ray crystallographic structures of C domains of class I PDEs reveal that they are primarily comprised of alpha-helices; three regions come together to form the catalytic pocket. Within the catalytic site, there are two prominent functional subdomains: one contains a novel binuclear metal-binding site that binds two divalent cation(s) and provides the catalytic machinery; the other subdomain provides interactions with the cN purine. The metals and cN apparently bind independently. The subdomains are closely juxtaposed in the tertiary structure in order to bind ligands and effect catalysis. Results of site-directed mutagenesis studies in PDE holoenzymes and X-ray

crystallographic structures of the C domains have identified important amino acids in each subdomain.

Metal Requirements

PDEs require divalent cation(s) to support catalysis. Class I PDEs contain two metals that are bound in close proximity and are critical to the catalytic process. Evidence indicates that an activated hydroxyl derived from solvent water and bridging the metals is inserted at the phosphate, thereby cleaving the phosphodiester bond. In two cGMP-specific PDEs (PDEs 5 and 6), Zn^{2+} is required for catalysis. Results of site-directed mutagenesis and X-ray crystallographic structures of most of the catalytic domains of class I PDEs indicate that these PDEs contain a tightly bound Zn^{2+} that is coordinated by histidines, aspartic acids, and water molecules. The second metal, which is more weakly bound, is coordinated through interactions with an aspartic acid and several water molecules that are, in turn, linked to histidines and aspartic acid. The metal occupying the second metal site in PDEs is still unclear and may vary among PDEs. Both Mg^{2+} and Mn^{2+} have been suggested to be the physiologically relevant cations at this second site, but this remains to be definitively demonstrated.

Features That Contribute to cN Specificity

The molecular basis that provides for the affinity and selectivity of PDEs for either cN is poorly understood. cAMP and cGMP interactions with the PDE catalytic sites share some common features but different topographies in the various sites dictate positioning of the respective cNs. There are two major types of interactions between cN substrates and PDE catalytic sites that contribute to the affinity of interaction, that is, hydrogen bonding with an invariant glutamine and hydrophobic stacking with residues that sandwich the purine. Based on X-ray crystallographic structures of isolated C domains of PDEs, it was suggested that the invariant glutamine forms two hydrogen bonds with either cGMP or cAMP and that constraint in the orientation of that glutamine side chain determines specificity for interaction with the guanine or adenine in cGMP or cAMP, respectively. Results of site-directed mutagenesis studies in PDE5 and PDE11 support a single hydrogen bond with substrates, and a mutation in PDE5 allowing for free rotation of the invariant glutamine side chain does not improve affinity for cAMP as would be predicted from the model. Results of X-ray crystallographic studies of PDEs 2, 9, and 10 also support a single hydrogen bond between the glutamine and the purine. The combined results indicate that multiple factors are likely to dictate specificity for either cGMP or cAMP.

In solution, cNs are in equilibrium between two conformations, *syn* and *anti*, based on orientation between the purine and ribose moieties. The preference of the catalytic site for binding cAMP or cGMP in either the *syn* or *anti* configuration varies among PDE families, but the *anti* conformer is most commonly preferred. Large substitutions on the ribose 2'-OH or the N-1 and C-2 positions of the purine are well tolerated by the catalytic sites of both cGMP-specific PDEs 5 and 6 and the dual-specificity PDEs 1, 2, and 11. In addition to the preference of

particular PDEs for the *syn* or *anti* conformation, it has now been shown that, even in dual-specificity PDEs, such as PDE10, which binds cAMP and cGMP in the *syn* conformation, the orientation of the purine ring of cAMP or cGMP can differ in the catalytic pocket presumably in order to optimize contacts in the site.

Interaction with Inhibitors

Most of the known PDE inhibitors compete with cN for access to the catalytic site. Specific structural features in the catalytic sites of PDEs provide for interaction with different inhibitors. Many inhibitors that compete for access to the catalytic site of cGMP-hydrolyzing PDEs mimic the structure of cGMP. This is true for three potent inhibitors of PDE5, that is, sildenafil (Viagra), vardenafil (Levitra) and udenafil (Zydena); tadalafil (Cialis) also competes with cGMP for the catalytic site, but its structure is less closely patterned on that of cGMP, and it forms different contacts with PDE5 than occur with sildenafil or vardenafil. Results from site-directed mutagenesis studies indicate that sildenafil and vardenafil utilize many amino acid contacts that provide for interaction of cGMP with PDE5. Affinity of PDE5 for these inhibitors is ~1000–25 000 times greater than for cGMP mainly due to the formation of many additional contacts between the respective inhibitors and the protein, but contacts common to cGMP and the inhibitors may be strengthened as well.

PDEs 5, 6, and 11 are closely related and share ~50% amino acid sequence homology. Sildenafil and vardenafil inhibit both PDEs 5 and 6 but have ~4–10-fold lower affinity for PDE6 isoenzymes than for PDE5; both are very weak inhibitors of PDE11. By contrast, tadalafil (Cialis) potently inhibits PDE5, is ~40-fold less effective against PDE11, and has little effect on PDE6. PDE1, a dual-specificity PDE, is inhibited by sildenafil with ~100-fold lower potency than that for PDE5. The catalytic sites of PDEs 1, 5, and 6 have similar preferences for cN analogs, so it is likely that sildenafil and vardenafil exploit shared structural features among these PDEs. By contrast, some other inhibitors selectively inhibit the dual-specificity PDEs 1, 2, and 3 and are ineffective against PDEs 5 and 6. The approach for development of new selective PDE inhibitors will continue to use X-ray crystallographic structures of catalytic sites as well as the traditional medicinal chemistry approach to map patterns of molecular selectivity for compounds that preferentially inhibit particular cGMP PDEs. PDE6 isoenzymes are novel in that they are inhibited by members of a specific protein family, $\text{P}\gamma$. $\text{P}\gamma$ inhibitor proteins appear to be entirely specific for the PDE6 isoenzymes, and like the PDE6 isoenzymes, expression of these proteins is restricted to photoreceptor cells and the pineal gland.

Regulation of cGMP-Hydrolyzing PDEs

cGMP-hydrolyzing PDEs are regulated by both short- and long-term regulatory mechanisms. These include ligand activation, for example, Ca^{2+} /calmodulin (PDE1) and cGMP binding to allosteric sites provided by GAFs (PDEs 2, 5, and 6); phosphorylation (PDEs 1, 3, 5, and 11) (Figure 3); selective subcellular localization; and modulation of PDE gene expression and protein levels. In a physiological setting, these frequently

work in concert to provide sensitive control of PDE activities in response to many stimuli.

Each monomer of PDEs 2, 5, 6, 10, and 11A4 contains two homologous GAFs (GAF-A and GAF-B) that are evolutionarily distinct from the catalytic sites. GAF-B in PDE2 and GAF-A in PDE5, PDE6, and PDE11 provide for allosteric cGMP binding whereas GAF-B in PDE10 provides for allosteric cAMP binding. Molecular determinants for cGMP interaction with the catalytic site differ markedly from those for cGMP binding to GAFs. In PDE2, cAMP binds to GAF-B but with >10-fold lower affinity than that for cGMP binding. However, cAMP is a very poor competitor for cGMP binding in PDEs 5, 6, and 11. In the X-ray crystallographic structure of the PDE2 R domain, cGMP is almost entirely buried within the GAF-B site. The tight fit of cGMP agrees well with the fact that few cGMP analogs compete with cGMP binding at this site.

Characteristics of cGMP-Specific Class I PDEs

PDE5

PDE5 is known as the cGMP-binding, cGMP-specific PDE. There are three PDE5 isoenzymes derived from a single gene. PDE5 has >100-fold selectivity for cGMP over cAMP at both its catalytic and allosteric sites; it is a homodimer of ~100 kDa subunits; each R domain contains two GAFs (A and B). GAF-A provides for allosteric cGMP binding, which activates catalysis. Ligand binding to GAF-B has not been shown, but this GAF provides important functional and regulatory features to the enzyme, and both GAFs contribute to dimerization. The K_m for cGMP hydrolysis is ~3 μM and the $V_{\max}$ is ~5 $\mu\text{mol min}^{-1} \text{mg}^{-1}$. PDE5 is abundant in smooth muscle cells, gastrointestinal epithelial cells, platelets, and certain neuronal cells. It is typically coexpressed with other components of cGMP signaling, including PKGs and GCs. Catalytic activity is stimulated by cGMP binding to the allosteric cGMP-binding site, phosphorylation of Ser-102 near the N terminus, and chemical reduction. Phosphorylation occurs in intact tissues in response to elevation of cGMP and PKG action and is enhanced by cGMP binding to GAF-A. PKA can phosphorylate Ser-102 but with >10-fold lower efficacy.

PDE5 is the major cGMP-hydrolyzing PDE in platelets, lung, and the vascular smooth muscle (VSM) of the penile corpus cavernosum (PCC). Sildenafil (Viagra and Revatio), tadalafil (Cialis), vardenafil (Levitra) or udenafil (Zydena) blocks cGMP breakdown by PDE5. In the presence of ongoing cGMP synthesis, these inhibitors promote accumulation of intracellular cGMP and relaxation of the VSM of blood vessels in the lung and PCC. The relaxation of VSM increases blood flow and capacitance of the vascular structures in the PCC, thereby facilitating accumulation of blood and improved erectile function; relaxation of VSM in pulmonary blood vessels increases perfusion of the lung, thereby increasing oxygen exchange and decreasing back pressure on the right heart. Sildenafil has recently shown promise in treatment of cardiac hypertrophy resulting from pressure overload diseases involving the vasculature and other maladies.

PDE6

PDE6 occurs only in the pineal gland and outer segments of mammalian retinal photoreceptor cells. PDE6 in cone and

rod photoreceptor cells provides for the visual response to high- and low-intensity light, respectively. In both cell types, the PDE6 isoenzymes are highly abundant. Rods contain PDE6 $\alpha\beta$, a heterodimer of ~100-kDa subunits that is bound to two inhibitory $P\gamma$ subunits specific for the rod enzyme. Cones contain PDE6 $\alpha'\alpha'$, a homodimer of ~100-kDa subunits that is complexed with two inhibitory $P\gamma$ subunits specific for the cone enzyme. In the absence of light, the catalytic activities of PDE6 $\alpha\beta$ and PDE6 $\alpha'\alpha'$ are inhibited by the respective $P\gamma$ s. Activated PDE6 isoenzymes have high catalytic activity ($V_{\max}$ ~300 $\mu\text{mol min}^{-1} \text{mg}^{-1}$) and K_m ~35 μM . GAF-A in each PDE6 subunit provides for allosteric cGMP binding and a major portion of cGMP in the photoreceptors is bound to PDE6 isoenzymes.

In the dark, cGMP in photoreceptors is high and binds to a cGMP-gated cation channel, which then allows for increased conductance of a 'dark current'. When light strikes the retina, transducin, a G protein, is activated, and the α -subunit of transducin interacts with the $P\gamma$ in each PDE6 isoenzyme to relieve $P\gamma$ -mediated inhibition. The resulting burst of PDE6 activity causes a sudden drop in cGMP. At low cGMP, cGMP dissociates from the channel, which then closes and the 'dark current' is terminated. The resulting change in the membrane potential produces the sensation of light. PDE6 isoenzymes are the only PDEs that have been found thus far to be regulated by a G protein. Many other complex regulatory processes also contribute to PDE6 functions and provide for optimal visual response to a broad range of light intensities.

PDE9

Little is known about the tissue distribution or physiological role of PDE9. It is highly selective for cGMP and has a K_m of 0.1–2 μM for cGMP versus 230 μM for cAMP. It is inhibited by zaprinast (IC_{50} ~35 μM) but is insensitive to a wide range of other PDE inhibitors including sildenafil, vinpocetine, IBMX, and dipyridamole. Inhibitors that target PDE9 may prove to be useful in treatment of Alzheimer's disease.

Characteristics of Class I Dual-Specificity PDEs

A number of mammalian PDEs (PDEs 1–3, 10, and 11) hydrolyze both cGMP and cAMP. The physiological role of each PDE in hydrolyzing the two nucleotides is likely to be complex. Activities of these PDEs toward either cGMP or cAMP in cells will reflect the respective K_m and $V_{\max}$ values for each. Selective action toward one nucleotide can occur simply by mass action as the level of that cN increases in the cell. For example, if the cGMP/cAMP content of a tissue selectively changes, increased hydrolysis of one nucleotide (e.g., in response to elevated amounts of that nucleotide) would tend to decrease hydrolysis of the other nucleotide through simple competition for the catalytic site. As a result, the concentration of the second cN would increase and activate its signaling pathway.

PDE1

The PDE1 family is regulated in the short term by Ca^{2+} /calmodulin binding following elevation of Ca^{2+} derived primarily from extracellular sources, and in the long term by

changes in PDE protein level (Figure 3). PDE1 isoenzymes are widely expressed and are abundant in brain, heart, VSM, testis, macrophages, lymphocytes, and liver. PDE1 isoenzymes catalytic subunits occur as dimers, and each monomer is comprised of two calmodulin-binding sites, an autoinhibitory subdomain, and a catalytic domain. Ca^{2+} /calmodulin binding relieves autoinhibition and increases the $V_{\max}$ with no change in K_m . Activities of the PDE1 family are implicated in diverse processes that include regulation of smooth muscle proliferation, learning and memory, cardiac hypertrophy, and olfaction.

The PDE1 isoenzymes (PDE1A, 1B, and 1C) are derived from three genes and are represented in tissues by many splice variants that substantially differ in size. Among these isoenzymes, the relative affinities and catalytic rates for cGMP and cAMP vary considerably. Affinities for certain inhibitors and sensitivities to stimulation by Ca^{2+} /calmodulin also vary. In tissues containing primarily one isoenzyme, the relative hydrolytic contribution of the PDE1 family to breakdown of cAMP or cGMP will reflect the kinetic features of this dominant PDE1. PDE1 isoenzymes are primarily cytosolic, but they are also found in association with the plasma membrane and other particulate cellular components. Depending on location in the cell, members of the PDE1 family can differentially respond to selective changes in Ca^{2+} signaling and thereby provide for variations in the spatial and temporal changes in cGMP and/or cAMP levels. Inhibitors that show selectivity for PDE1 isoenzymes include vinpocetine, IC224, and SCH51866.

PDE2

PDE2 is known as the cGMP-stimulated PDE, and its three variants are derived from a single gene. It is a homodimer comprised of ~105-kDa monomers and is expressed in many tissues including brain, heart, liver, adrenal gland, macrophages, vascular endothelial cells, and platelets. $V_{\max}$ values for hydrolysis of cAMP and cGMP are similar ($150 \mu\text{mol min}^{-1} \text{mg}^{-1}$) and K_m values differ nearly twofold ($15\text{--}30 \mu\text{M}$ for cGMP vs. $30\text{--}50 \mu\text{M}$ for cAMP). cGMP binds to GAF-B in the R domain and stimulates breakdown of either cAMP or cGMP at the catalytic site. PDE2 can, therefore, potentially lower either or both cNs. PDE2 is abundant in adrenal cortex cells, which produce aldosterone in response to cAMP elevation. In these cells, elevation of cGMP results in cGMP binding to the PDE2 GAF-B, causing increased cAMP hydrolysis and decreased aldosterone production. A similar physiological effect to increase cGMP hydrolysis by cGMP binding has not been experimentally demonstrated, but it is likely to occur and would provide a negative feedback pathway for regulation of cGMP level. PDE2 has also been shown to be important in regulation of cGMP pools near the plasma membrane in cardiomyocytes and is implicated along with PDE3 in control of permeability of the vascular endothelium.

PDE3

PDE3 is abundant in many tissues and occurs as two groups of isoenzymes (PDE3A and 3B) that are largely membrane bound and exhibit ~80% amino acid sequence identity in their C domains. Both hydrolyze cAMP with a greater $V_{\max}$ than that for cGMP, but there is little difference in K_m values for the cNs. PDE3B is activated by phosphorylation in its R domain. Historically, the moniker for PDE3 was the

'cGMP-inhibited PDE', but this is a misleading descriptor because cGMP 'inhibits' cAMP hydrolysis by competing for access to the catalytic site. The action of PDE3 isoenzymes is implicated in myriad physiological processes including cardiovascular functions, lipolysis, carbohydrate metabolism, insulin secretion, and platelet disaggregation. In some tissues, evidence suggests that some effects of cGMP may be mediated, at least in part, through increased cAMP signaling due to cGMP competition with cAMP hydrolysis by PDE3. Elevation of cGMP would increase its effectiveness in competing with cAMP for the PDE3 catalytic site, thereby 'protecting' cAMP from hydrolysis.

The catalytic activities of PDE3B isoenzymes are activated by phosphorylation by PKA as well as by the $\text{PI}_3\text{K}/\text{PKB}$ pathways in response to a number of hormone signals. This activation produces a negative feedback loop to blunt or terminate elevations in cAMP and cAMP-signaling. In addition to this negative feedback role, PDE3 is activated by insulin and other signaling molecules by stimulation of the $\text{PI}_3\text{K}/\text{PKB}$ pathway in adipose tissue and liver, thereby lowering cAMP level. This results in inhibition of adipose tissue lipolysis or liver glycogenolysis and gluconeogenesis. PDE3 is physiologically important in many tissues including heart, platelets, oocytes, smooth muscle, liver, and adipocytes. There are a number of inhibitors (cilostazol, milrinone, and amrinone) that are selective for PDE3 isoenzymes; cilostazol (Pletal) is used clinically for treatment of intermittent claudication and milrinone (Primacor) is used for treatment of heart failure.

PDE10

Little is known about the physiological functions or regulation of PDE10. PDE10 isoenzymes (PDE10A1-4) are derived from one gene and are most abundant in neural tissues including the striatal area, hippocampus, cerebellum, and thalamus; it may play a particularly prominent role in striatal medium spiny neurons. Transcripts are also found in non-neural tissues including testis, thyroid, pituitary, heart, prostate, liver, and skeletal muscles. It has higher affinity for cAMP versus cGMP (K_m values ~0.05 and $3 \mu\text{M}$, respectively), but the $V_{\max}$ for cGMP is ~4 times that for cAMP. PDE10 R domain contains GAFs, and cAMP binds tightly to GAF-B. However, a regulatory function for this association in PDE10 holoenzyme has not been established. PDE10A2 is phosphorylated by PKA at Thr-16; this promotes relocation of PDE10 from the Golgi to the cytosol. Based on its abundance and location in the brain as well as changes in various disease models, PDE10 has been considered as a target for treatment of dysfunctions such as schizophrenia, obsessive-compulsive disorders, addictions, Parkinson's disease, and Huntington's disease. It is potently inhibited by papaverine ($\text{IC}_{50} \sim 30 \text{ nM}$) as well as by the nonspecific inhibitors 3-isobutyl-1-methylxanthine (IBMX), dipyridamole, and zaprinast.

PDE11

PDE11 is closely related to PDE5 (50% homology). Very little is known about its physiological function or biochemical regulation. There are four isoenzymes (PDE11A1-4) derived from one gene; PDE11A4 is the only form detected thus far in

human tissues and is most abundant in prostate, skeletal muscle, pituitary, heart, and liver. The R domains of PDE11 isoenzymes contain one, two, or partial GAFs, and cGMP binds with high affinity to GAF-A. However, no regulatory role has been established for this interaction. PDE11 hydrolyzes cGMP and cAMP at similar rates, but K_m for cAMP is slightly lower than that for cGMP (0.5 vs. 1 μ M, respectively). The most potent inhibitor of PDE11 is tadalafil (Cialis) ($IC_{50} \sim 73$ nM); it is also inhibited by dipyrindamole ($IC_{50} \sim 400$ –900 nM), vardenafil ($IC_{50} \sim 840$ nM) and sildenafil ($IC_{50} \sim 3800$ nM).

Characteristics of Class II PDEs

Class II PDEs have now been identified in various lower eukaryotes, fungi, and bacteria and based on analysis of the sequences of their catalytic domains have been subdivided into two related groups of PDEs. They share no apparent homology with class I PDEs, and the enzymatic characteristics of most of these enzymes have not been studied. The catalytic domains of the two subgroups vary in length, and the amino acid sequence of one of the groups resembles that of the metallo- β -lactamases. No X-ray crystallographic structures are available, and studies on the effects of site-directed mutagenesis on enzyme functions are limited. The catalytic domains of class II PDEs contain a Zn^{2+} -binding motif that is different from the Zn^{2+} -binding motif in class I PDEs, and this motif is thought to provide critical features for hydrolysis of cN. This class of PDEs can hydrolyze cGMP and cAMP and, in some instances, have catalytic action on polynucleotides.

Catalytic Activity

Like class I PDEs, class II PDEs require divalent cation(s) for catalytic activity and exhibit varying selectivities for cGMP and cAMP as substrates. Catalytic activity in a class II PDE from *Saccharomyces cerevisiae* has been shown to require Zn^{2+} . Class II PDEs that are known to hydrolyze cGMP include a dual-specificity PDE from *Vibrio fischeri* that is expressed in the periplasmic space and hydrolyzes cAMP and cGMP with very high turnover rates; dual-specificity PDEs from *Dictyostelium discoideum* (DdPDE1, DdPDE6, and DdPDE7); and a cGMP-specific PDE from *Dictyostelium discoideum* (DdPDE5), which is the major cGMP-degrading enzyme in the intact cell (Figure 4). Many of these PDEs are insensitive to IBMX, a nonspecific inhibitor of most class I PDEs. DdPDE1 in *Dictyostelium* can be exposed on the cell surface or secreted into the medium; although it is a dual-specificity PDE, its main function is apparently to hydrolyze cAMP in the extracellular milieu.

Regulation

Class II PDEs can be regulated by short- and long-term processes. The catalytic activities of two *Dictyostelium* PDEs (DdPDE5 and DdPDE6) are increased by cN binding to site (s) in their R domains (Figure 4). In DdPDE5, catalytic activity is stimulated by allosteric cGMP binding, whereas allosteric binding of either cGMP or cAMP stimulates catalysis by

Figure 4 Schematic depiction of select class II cGMP-hydrolyzing PDEs. Arrangements of functional domains are shown for a monomer. The allosteric cN-binding sites belong to the CAP-related family of cN-binding proteins and are distinct from the allosteric cGMP-binding sites in class I PDEs.

DdPDE6. This resembles the stimulatory effect of cGMP on catalysis in class I PDEs 2 and 5. However, GAFs are absent in class II PDEs. Instead, both contain two CAP-related cN-binding domains that are located C-terminal to the catalytic domain (Figure 4). Thus, despite no evolutionary relatedness between class I and II PDEs, similar regulatory mechanisms are used, and, remarkably, evolutionarily distinct motifs and arrangements of the motifs in the structures have been employed. These developments are striking examples of convergent evolution. Moreover, regulation of the expression both classes of PDEs occurs throughout the growth cycle and aggregate phases of *Dictyostelium*.

Concluding Remarks

cGMP levels are physiologically modulated through the action of cGMP-specific PDEs and dual-specificity (cGMP and cAMP) PDEs. Both must be considered when studying physiological changes in intracellular cGMP. Two evolutionarily unrelated classes of these enzymes exist, but only class I is present in mammals. Several mammalian PDEs have been successfully targeted by new medications for treatment of various diseases.

Glossary

Autoinhibition The effect of one region of an enzyme blocking the action of the catalytic site of another region of that same enzyme.

Autophosphorylation Protein kinase-catalyzed transfer of the γ -phosphate of adenosine triphosphate (ATP) to a residue within the protein kinase itself.

Consensus phosphorylation sequence The amino acid sequence that contains the determinants that provide for the

specific phosphorylation of that sequence by a particular protein kinase.

Heterophosphorylation Protein kinase-catalyzed transfer of the γ -phosphate of ATP to another protein substrate.

Pseudosubstrate sequence An amino acid sequence that closely resembles the consensus phosphorylation sequence for a protein kinase substrate but lacks the residue that can be phosphorylated.

Introduction

Upon elevation of 3',5'-cyclic monophosphate (cAMP) or guanosine 3',5'-cyclic monophosphate (cGMP) in cells, these nucleotides bind to numerous proteins including the cyclic nucleotide-dependent protein kinases, cyclic nucleotide-gated channels, and cyclic nucleotide phosphodiesterases (PDEs); cAMP also binds to exchange proteins that are activated by cAMP (Epacs). The actions of these target proteins elicit a panoply of biological changes in cells, but the cAMP- and cGMP-dependent protein kinases (PKAs and PKGs, respectively) play a central role in mediating the effects of the cyclic nucleotides. Intracellular levels of cAMP and cGMP are primarily determined by the balance between their synthesis and breakdown. They are synthesized from either adenosine triphosphate (ATP) or guanosine triphosphate (GTP) by adenylyl cyclases or guanylyl cyclases, respectively, in response to first-messenger signals in the body (e.g., hormones, neurotransmitters, and environmental stimuli), and they are broken down by cyclic nucleotide PDEs. The important concept of second-messenger signaling as occurs with cAMP and cGMP is that many hormones, neurotransmitters, or other stimuli can elicit their physiological effects without entering the cell. Second-messenger signaling was first demonstrated for cAMP.

even slight variations in the cellular concentration of cAMP or cGMP can alter the activation state of the respective kinase significantly.

In addition to their breakdown by PDEs, both nucleotides can be extruded from cells. The action of PDEs is the major mechanism for rapid lowering of cyclic nucleotides in the cell (Figure 2). Following activation by cyclic nucleotide binding, PKA or PKG then catalyzes transfer of the γ -phosphate of ATP to selected serines or threonines that are located in a consensus sequence in many cellular proteins; this process is known as phosphorylation. The covalent attachment of phosphate to these proteins converts them into phosphoproteins, a process known as heterophosphorylation, because in this case PKA or PKG phosphorylates proteins other than itself. When PKA or PKG catalyzes the covalent attachment of a phosphate to sites within its own structure, this is known as autophosphorylation. The phosphoproteins produced by these modifications frequently exhibit changes in activities, subcellular localizations, and interactions with other cellular components, including other proteins, DNA, RNA, and lipids. The altered functions of these proteins that have been phosphorylated by PKA or PKG mediate the changes induced by many hormones, neurotransmitters, and other stimuli, including those in metabolism, gene transcription, neurotransmission, blood pressure, and fluid homeostasis.

Cyclic Nucleotide-Dependent Protein Kinases as Intracellular Receptors for cAMP and cGMP

The molecular structures of cAMP and cGMP are very similar (Figure 1), but the structural distinctions between these compounds provide for selective binding to and activation of PKA and PKG, respectively, which then mediate many of the biological actions of these two second messengers (Figure 1). PKA and PKG belong to the family of ABC kinases, are closely related, and share many functional and regulatory characteristics. In the presence of small amounts of cAMP or cGMP (e.g., concentrations ranging from 10^{-8} to 10^{-7} M), these kinases are activated by binding the cyclic nucleotide so that

Overall Structures of Cyclic Nucleotide-Dependent Protein Kinases

There are several isoforms of PKA and PKG, but all have a similar organization of their functional domains (Figure 3). Both are chimeric proteins comprising a regulatory domain and a catalytic domain, and within each of these there are several subdomains that provide for specific functions. PKA regulatory and catalytic domains are located on separate subunits, the regulatory (R) and catalytic (C) subunits, respectively. In PKG, the regulatory and catalytic domains are on a single polypeptide chain. Phosphorylation at a threonine in the active sites of PKG and PKA C subunit is required for

Figure 1 Structural models of (a) cGMP and (b) cAMP. cGMP and cAMP differ only in their purine rings. These differences in the purine ring provide for the specificity with which each kinase interacts preferentially with that nucleotide. The cyclic phosphate moiety is required for binding to the cyclic nucleotide-binding sites on PKG and PKA, and the 2'-OH of the ribose provides an important contact in the respective sites. There are two conformations of these nucleotides, *syn* (shown) and *anti*, due to rotation around the bond linking the purine and the ribose. Both PKA and PKG bind the *syn* conformer. Important features of cGMP that contribute to its interaction with PKG include the amino group at C-2 (which interacts with a conserved threonine in sites preferring cGMP), the oxygen at C-6, and a protonated N-1. As compared with cGMP, cAMP has a single substitution on the purine (i.e., an amino group at C-6 and no protonation at N-1).

Figure 2 The balance between cyclase and phosphodiesterase activities determines cyclic nucleotide levels in the cell. cAMP and cGMP are synthesized from either (a) ATP by adenylyl cyclase or (b) GTP by guanylyl cyclase; when the activities of these cyclases are increased, more cAMP or cGMP is produced. The breakdown of the cyclic nucleotides is catalyzed by cyclic nucleotide phosphodiesterases (PDEs), and the activities of these enzymes lower cAMP and cGMP.

activity. Both families of kinases form dimers through interactions among residues near the N terminus within their regulatory domains. However, the salient features of regulation and catalysis are largely retained in monomeric forms of PKG and in PKA formed by the combination of a single R subunit and C subunit.

Although dimerization is not necessary for many PKA functions, it is required for anchoring a portion of the PKA to

specific subcellular compartments through a family of proteins known as A-kinase anchoring proteins (AKAPs). In many instances, anchoring of PKA brings it into close proximity with substrates, thereby facilitating rapid and efficient cAMP signaling. Likewise, dimerization of PKGs is not necessary for many of PKG-mediated functions; however, in some instances, the N-terminal dimerization domain of PKGs provides for specific interaction with certain substrates allowing for PKG-mediated phosphorylation. PKA R subunits are aligned in an antiparallel arrangement within the dimer and use hydrophobic interactions, whereas PKG monomers are aligned in a parallel arrangement within the dimer and use interactions formed by an extended leucine zipper motif.

cAMP-Dependent Protein Kinase

PKA is present in the cytosolic and particulate fraction of all mammalian tissues and occurs at concentrations ranging from 0.2 to 2 μM . It is a tetramer comprising two C subunits and two R subunits (R₂C₂) (Figure 3). There are three genes for mammalian C subunit (C α , C β , and C γ), each is $\sim 36\,000$ Da. There are four major genes for R subunits (RI α , RI β , RII α , and RII β), each is $\sim 45\,000$ Da. Nomenclature for PKAs is based on the R subunits; PKAs containing RI subunits are called type I PKA, and those containing RII subunits are called type II PKA. Both types may contain either form of C subunit. Most tissues contain both types of PKA, and while either type can frequently mediate cAMP action, selective colocalization of one form with a particular substrate may be required. Type II PKA is abundant in the cytosol and is also commonly anchored in membrane compartments. Although type I PKA is also anchored in some instances, it is

Figure 3 Working models of (a) PKAs and (b) PKGs, depicting the overall organization of the functional domains within these enzymes. The major isozymic forms that are products of different genes for each of the kinases are listed below each model. C_γ is the product of a pseudogene that is not present in all species. The alignment of the low-affinity and high-affinity cyclic nucleotide sites within PKA R subunit is the same for all known PKAs. The linear arrangement of the cGMP-binding sites in PKG-II is the same as that found in PKAs. However, in PKG-I, the sites are transposed so that the more N-terminal site is the high-affinity cGMP-binding site and the more C-terminal position is the low-affinity site.

predominantly cytosolic. The RI and RII content of a particular tissue varies among species.

In the absence of cAMP, an R subunit interacts with a C subunit with high affinity (~ 0.2 nM) and suppresses its catalytic activity through a process known as autoinhibition. Cyclic AMP binding to two cAMP-binding sites on an R subunit causes a large conformational change that decreases the R subunit affinity for C subunit by 10 000- to 100 000-fold. An active monomeric C subunit dissociates from the complex and can diffuse throughout the cell, including the nucleus, which excludes R subunits and PKA holoenzymes. The diffusibility of the C subunit provides for the mechanism by which cAMP elicits its effect in a number of systems. The R subunits remain dimerized and, if anchored to AKAPs, they remain anchored.

X-ray crystallographic structures of the isolated C subunit, R subunits, and complexes between R and C subunits have provided myriad molecular insights into structure/function relationships of PKAs. Moreover, these results have advanced understanding of all kinases that are related to PKA. The catalytic site of the C subunit is formed at the interface of two lobes where the γ -phosphate of ATP is transferred to the protein substrate. The smaller, more N-terminal lobe makes most of the contacts with Mg^{2+} /ATP. The larger, more C-terminal lobe makes most of the contacts that precisely position the protein substrate in the catalytic cleft and also forms extensive contacts with the R subunit. The binding of Mg^{2+} /ATP and a protein substrate into the catalytic cleft allows a complex set of enzymatic actions that act in concert to rapidly transfer the phosphate from ATP to substrate. Release of the product, adenosine diphosphate (ADP), is rate limiting in most cases.

In order to efficiently transfer the phosphate to a peptide or protein, PKA strongly prefers an amino acid sequence of -ArgArgXSer/ThrX- (called a PKA consensus phosphorylation site) in its substrates. The sequence at the phosphorylation site provides in large part for the efficiency with which the C subunit phosphorylates a protein, but co-localization of PKA and some substrates via interactions with AKAPs also contribute importantly. Although arginines (Arg) are highly preferred in the two indicated positions, some variation is tolerated. The amino acids in the positions marked as X can affect the affinity of the C-subunit interaction with a substrate.

Each R subunit contains several subdomains. These include an N-terminal dimerization/docking subdomain, which includes the autoinhibitory and autophosphorylation regions, and a cyclic nucleotide-binding subdomain that contains two cAMP-binding sites (A and B) arranged in tandem (Figure 3). In the absence of cAMP, a substrate-like sequence in the R subunit binds tightly to the catalytic site in the C subunit. Although other contacts also contribute to stabilizing the R-C interaction, this substrate-like sequence in the autoinhibitory domain competes with protein substrate binding and provides a major portion of the interactions that hold PKA in a catalytically inactive form in the absence of cAMP. This is known as autoinhibition. The binding of cAMP to both cAMP-binding sites in each R subunit disrupts the R-C interaction.

Most commonly, the PKA tetramer contains a single type of R subunit (either RI or RII). RII subunits contain a sequence in the autoinhibitory domain that mimics a PKA substrate motif, and the serine in this sequence can be autophosphorylated by the C subunit when the subunits are complexed (i.e., in the

absence of cAMP). Autophosphorylation of this site in RII increases its affinity for cAMP so that PKA can be activated at lower cAMP concentrations. Type I R subunits contain a pseudosubstrate sequence (-ArgArgXGlyX-) that is a substrate-like sequence lacking a phosphorylatable residue. Therefore, type I PKA R subunits cannot undergo autophosphorylation.

PKA plays a critical role in functions of all mammalian cells. As a result, it is likely that survival requires the presence of the PKA C subunit. A null mutation for all three C subunits in yeast is lethal. Mice carrying null mutations for either *C α* or *C β* are viable, but differ phenotypically; mice lacking either RI or RII subunits are also typically viable and differ phenotypically. These results suggest that these C subunits and R subunits have selectivity in some functions.

cGMP-Dependent Protein Kinase

PKGs play a central role in regulating smooth muscle tone, platelet aggregation, bone growth, neuronal plasticity, and water-salt homeostasis. Cellular concentration of PKG ranges from infinitesimally low to 4 μ M. There are two families of PKG (PKG-I and PKG-II) that are the products of separate genes. These families are rarely co-expressed and have selective functions because the phenotype of PKG-I-null mice differs substantially from that of PKG-II-null animals. PKG-I has two alternative splice variants (PKG-I α and PKG-I β) that vary in the N terminal ~100 amino acids and are frequently co-expressed. PKG-I is largely cytosolic, whereas PKG-II is membrane-bound through an N-terminal myristoyl group. The membrane association of PKG-II co-localizes PKG-II with intended substrates, thereby providing for specific phosphorylations that do not occur when PKG-II is in its soluble form. The PKG-I isoenzymes, PKG-I α and PKG-I β , are largely cytosolic, but they too are specifically localized in some cases. Where this has been studied, localization for PKG-I isoenzymes is selectively mediated through interactions involving their respective unique leucine zipper motifs and specific sites in other proteins, for example, the myosin-binding protein of myosin light chain phosphoprotein phosphatase. In many cases, the interaction is selective for either PKG-I α or PKG-I β , indicating that the specificity of the interaction involves sequences that are novel to that isoenzyme.

PKG regulatory domains contain several subdomains including an N-terminal dimerization subdomain involving a leucine zipper motif, a subdomain containing the overlapping autoinhibitory and autophosphorylation regions, and a cyclic nucleotide-binding subdomain that contains two cGMP-binding sites arranged in tandem (Figure 3). The role of dimerization is unclear because, at least for PKGI, the monomeric enzyme retains the salient features of the dimer. However, interactions within the PKGI leucine zipper that provide for dimerization also stabilize structural features in this region that confer PKGI localization with some substrates and may afford catalytic advantages for dimeric PKGI.

The autoinhibitory-autophosphorylation subdomain is located just C-terminal to the dimerization subdomain. This region accounts for autoinhibition of the catalytic site and contains multiple autophosphorylation sites, most of which do not resemble a consensus substrate sequence and are not

conserved among PKGs. Autophosphorylation of these sites is catalyzed by the catalytic domain within the same monomer and increases affinity for cGMP and basal activity. Autophosphorylation increases in the presence of cyclic nucleotide and promotes PKG ubiquitination and degradation through the proteosomal degradation system.

The mechanism of autoinhibition of PKGs also differs somewhat from that of PKA. The autoinhibitory subdomain of all PKGs contains either pseudosubstrate sequences, for example, -LysArgGlnAlaIle- in PKG-I β , or sequences that only weakly mimic a pseudosubstrate site, for example, -ArgAlaGlnGlyIle- in PKG-I α , where the italicized residue indicates the phosphorylation position in the autoinhibitory sequence. Furthermore, sequences outside the pseudosubstrate sequence contribute more prominently to the autoinhibition of both PKG-I and PKG-II compared to PKA.

Each of the two cGMP-binding sites of PKG are comprised of ~110 amino acids arranged in tandem. A small segment of protein connects the regulatory and catalytic domains of the enzyme. The structure of the catalytic domain is thought to closely resemble that of PKA because the enzymes are homologous. However, the two enzymes have numerous differences in regulatory mechanisms that are most likely due to differences in their overall structures. PKG catalytic activity, which is latent in the absence of cGMP, is increased upon cGMP binding, which causes a marked elongation of the PKG monomer and relief of autoinhibition.

Cyclic Nucleotide-Binding Specificity and Affinity

The two homologous cyclic nucleotide-binding sites (~110 amino acids each) in PKA and PKG are products of an ancient gene duplication that occurred prior to the divergence of these proteins. The sites are evolutionarily related to a bacterial cAMP-binding protein, the catabolite-gene-activating protein (CAP) family of cyclic nucleotide-binding proteins. The cyclic nucleotide-binding sites of cyclic nucleotide-gated channels and exchange proteins directly activated by cAMP (Epacs) are also members of this family. In both PKA and PKG, the two intra-subunit sites differ approximately 10-fold in their affinities for cyclic nucleotide binding and also differ in specificities for cyclic nucleotide analogs. In PKA RI and RII subunits, the more N-terminal site has a lower affinity for cAMP (fast cAMP dissociation) compared to the more C-terminal site (slow cAMP dissociation) (Figure 3). In PKG-II, the kinetically different cGMP-binding sites are arranged as in PKA, but in PKG-I the high-affinity site is the more N-terminal site. Full activation of either PKA or PKG requires saturation of all the cyclic nucleotide-binding sites.

PKA and PKG have a 50- to 200-fold selectivity for cAMP and cGMP, respectively, and most commonly the cellular effect of cAMP or cGMP is mediated by the respective kinase. However, in several systems, cAMP or cGMP has been shown to activate the other kinase through a process known as cross-activation. In the X-ray crystallographic structure of the PKA R subunit, cAMP is bound in a deep pocket within each site, and several conserved amino acids (glutamate, arginine, and several glycines) provide direct contact with the cyclic nucleotide or contribute to critical structural features of the site. In sites

preferring cGMP, an invariant threonine provides a major portion of the selectivity for cGMP by interacting with the 2'-amino group in the purine (Figure 1), but an X-ray crystal structure has not been determined for PKGs. Hydrophobic amino acids in each of the sites contribute importantly to the affinity with which cyclic nucleotide is bound.

Substrate Specificities of PKA and PKG

PKA and PKG-I share many similarities in substrate specificities, and the consensus sequence for phosphorylation by either enzyme is defined as -ArgArgXSer/ThrX-. These kinases can frequently phosphorylate the same proteins *in vitro*, although there are differences. PKG-I phosphorylates numerous proteins in sites that do not conform to this ideal consensus phosphorylation sequence; these sites are not phosphorylated well by PKA. A phenylalanine located C-terminal to the phosphorylation site strongly discriminates against PKA phosphorylation, but not that of PKG, and a basic amino acid C-terminally adjacent to the phosphorylation site favors phosphorylation by PKG-I. The substrate specificity of PKG-II is quite different from those of PKG-I and PKA.

Negative Feedback and Feed-Forward Control of Cyclic Nucleotide Pathways

A two- to fourfold increase in either cAMP or cGMP typically accounts for the physiological responses to these nucleotides, although larger increases can occur in some instances. Negative feedback control mechanisms restrict the magnitude or persistence of cyclic nucleotide signaling, whereas feed-forward mechanisms potentiate the response to cyclic nucleotide elevation. Both types of mechanisms have been established for the cAMP- and cGMP-signaling cascades (Figure 4). First, PKA and PKG can phosphorylate and activate PDEs, which accelerates the breakdown of cyclic nucleotides, thereby favoring inactivation of the kinases. Second, when the beta 2-adrenergic receptor is bound to an agonist such as epinephrine, it is rapidly phosphorylated by PKA, as well as by the beta-adrenergic receptor kinase (BARK), resulting in desensitization to further stimulation by agonists. For cAMP signaling, both processes provide for a powerful negative feedback response to blunt the effects of elevated cAMP. Elevation of cGMP promotes autophosphorylation of PKGI α , which targets the enzyme for ubiquitination and degradation, thereby blunting the cGMP-signaling in those cells.

Figure 4 Mechanisms involving phosphorylation that contribute to modulation of the cAMP- and cGMP-signaling pathways. Feedback control refers to processes that tend to alter the overall effectiveness of signaling through cyclic nucleotide pathways. Negative feedback control mechanisms decrease the effectiveness of the cyclic nucleotide signal; these include increased activities of cyclic nucleotide phosphodiesterases (PDE activity) that break down the cAMP and cGMP, decreased cAMP synthesis by adenylyl cyclases that are coupled to G proteins, and increased activities of phosphoprotein phosphatases that remove phosphates from phosphoproteins that have been phosphorylated by PKG. Feed-forward control (i.e., positive feedback control) mechanisms enhance the effectiveness of the signal. These include autophosphorylation by PKA and PKGI, which increases the affinity of these enzymes for the respective cyclic nucleotides as well as increasing catalytic activity. In addition, PKA increases phosphorylation of the phosphoprotein phosphatase inhibitor-1, which inhibits a phosphoprotein phosphatase and blocks its effect of removing phosphate from phosphoproteins involved in the signaling pathway. Circled + and – denote effects that either increase or decrease as the levels of cyclic nucleotides increase or decrease; arrows, ↑ and ↓, denote a change in the catalytic activity of the indicated enzymes that is induced by PKA- or PKG-mediated phosphorylation or the state of phosphorylation of the phosphoprotein phosphatase inhibitor-1 in response to increased PKA activity.

Both the cAMP- and cGMP-signaling cascades also have feed-forward control because the autophosphorylation of type II PKA or PKG-I increases kinase activity and cyclic nucleotide-binding affinity. The cAMP system has an additional feed-forward control because PKA phosphorylates phosphoprotein phosphatase inhibitor-1 to produce a potent inhibition of phosphoprotein phosphatase action, thereby potentiating the effects of PKA phosphorylation.

Glossary

Cyclic nucleotide phosphodiesterases (PDEs) Enzymes that catalyze hydrolysis of the 3'-5'-phosphodiester bond of cyclic adenosine monophosphate (cAMP) and/or cyclic guanosine monophosphate (cGMP).

Desensitization Prolonged or repeated exposure of receptors to their ligands leads to reduction or loss of responsiveness,

either homologous desensitization with loss of responsiveness only to a specific ligand or heterologous desensitization with loss of responsiveness to multiple ligands.

Family-specific inhibitors Drugs that inhibit the activity of one phosphodiesterase (PDE) gene family with 10–100-fold greater potency than the activities of other PDE gene families.

Cyclic nucleotide phosphodiesterases (PDEs) constitute a large, diverse, and complex superfamily of metal hydrolases which cleave the 3',5'-cyclic phosphate bond of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), resulting in production of 5'-AMP and 5'-GMP, respectively. Based on differences in primary structures, PDEs have been divided into three major classes, I, II, and III. Class I PDEs, which contain a conserved catalytic domain (~250–300 amino acids), comprise the 11 structurally related, highly regulated, and functionally distinct mammalian gene families (PDEs 1–11). The class I catalytic domain contains a signature motif H(X)₃H (X)_{25–35}(D/E), which is also found in metal hydrolases. Class I PDEs are found in the parasites *Trypanosoma brucei* and *cruzi*, and in *Drosophila*, nematodes, yeast, and sponges. Class II PDEs, which are structurally unrelated to class I PDEs, are found in fungi, slime mold, and amoebae. Class III PDEs, with a β -lactamase-type catalytic domain, are found in *Dictyostelium discoideum*. The evolutionary relationship between the three PDE classes is not certain; this brief article focuses on mammalian class I PDEs.

By catalyzing hydrolysis of cyclic nucleotides, mammalian PDEs regulate their intracellular concentrations, and, consequently, their signaling pathways and myriad physiological effects, including myocardial contractility, visual transduction, vascular and airway smooth muscle relaxation, immune/inflammatory responses, cell proliferation and apoptosis, memory, and many others. There is a growing interest in identifying mutations in PDE genes that are associated with inherited diseases. The mammalian PDE superfamily is a major target for drug discovery in the treatment of clinically important diseases, with several PDE inhibitors being approved for use by the Food and Drug Administration (FDA), for example, PDE5 inhibitors for erectile dysfunction and pulmonary hypertension, and certain PDE3 inhibitors for acute heart failure and intermittent claudication.

Molecular Diversity

cAMP and cGMP are important intracellular second messengers that modulate many biological processes. The classical mechanism for transduction of cyclic nucleotide signals involves cyclic-nucleotide-induced activation of cAMP- and

cGMP-dependent protein kinases (PKA and PKG, respectively), with subsequent phosphorylation of critical downstream regulatory effectors. A second mechanism, however, assumed ever-increasing importance. It is clear that cyclic nucleotide-binding proteins can serve as direct mediators of many cyclic nucleotide actions, for example, cyclic-nucleotide-gated ion channels, cAMP-activated guanine nucleotide exchange factors (exchange protein activated by cAMP (EPACs)) which regulate Rap1 guanosine triphosphatases (GTPases), and several PDEs, especially PDEs 2, 5, 6, which contain allosteric, noncatalytic cyclic-nucleotide-binding sites.

Molecular genetics has revealed the diversity and complexity of the 11 mammalian PDE gene families (PDEs 1–11). PDE families differ in their primary amino sequences, substrate specificities, sensitivities to endogenous effectors and pharmacological agents, cellular functions, and mechanisms whereby they are regulated. Most PDE families comprise more than one gene; within these multiple families, closely related isoforms are generated from the same gene or different genes via alternative messenger RNA (mRNA) splicing or utilization of different promoters/transcription initiation sites. More than 20 PDE genes probably encode more than 50 PDE proteins. Some cells are relatively enriched in specific PDEs, for example, photoreceptor PDE6 is virtually exclusively expressed in the retina. Most cells, however, contain representatives of multiple PDE gene families, and different members of the same family, but in different amounts, proportions, and subcellular locations. Redundancy in PDEs, that is, the presence in the same cell of multiple enzymes which essentially perform the same reaction of hydrolyzing cyclic nucleotides, does not merely serve a survival or protective function, but rather allows cells to use distinct subsets of differentially regulated and localized PDEs to specifically and selectively regulate and segregate the generation, amplitude, duration, and compartmentation of cyclic nucleotide signals and actions. It is generally accepted that the cellular capacity to degrade cyclic nucleotides far exceeds their synthesis, and is a major factor in the very rapid turnover of intracellular cAMP and cGMP. The physiological significance and functional consequences of this rapid turnover, and concomitant heat generation (cyclic nucleotide hydrolysis is accompanied by release of $\sim 7 \text{ cal mol}^{-1}$), are not completely understood. This brief article discusses some

general characteristics of PDEs and then focuses on the cellular biology and diverse functions of different PDE isoforms and their potential as therapeutic targets.

Structure/Function Analyses

Catalytic Domain

Mammalian PDEs exhibit a common structural organization, with a conserved catalytic domain (~250–300 amino acids) in the C-terminal portion of the molecules and divergent regulatory domains and modules in N-terminal portions (Figure 1). Many PDEs exist as asymmetric homo- or heterodimers. The catalytic core, more highly conserved among members of the same gene family than different gene families, contains a signature motif [HD (X₂) H (X₄) N], common to all PDEs. Some PDE families are relatively specific for hydrolysis of cAMP (PDEs 4, 7, and 8); others for cGMP (PDEs 5, 6, and 9); and some exhibit mixed specificity for both cAMP and cGMP (PDEs 1, 2, 3, 10, and 11). Although methylxanthines inhibit almost all PDEs, relatively specific and selective inhibitors, that is, drugs that target individual PDE families with 10–100-fold greater potency than other PDE families, are available for several families, for example, PDEs 1, 2, 3, 4, 5, and 6. These family-specific inhibitors are important for both basic research and clinical applications.

Analyses of the crystal structures of the catalytic domains of seven PDE families (PDEs 1–5, 7, and 9) indicate that these core catalytic domains assume a compact structure consisting of 14 α -helices consisting of three subdomains. At the interface of these domains, the active site, which contains two metal-binding sites, forms a deep hydrophobic pocket lined with highly conserved residues. All families have a uniform conformation, except for PDE5. Cyclic nucleotide substrate specificity may be determined by the orientation (stabilized by a hydrogen-binding network) of an amide group of an invariant glutamine at the active site. Available data,

however, do not completely support this mechanism for all dual-specificity PDEs which hydrolyze both cAMP and cGMP. Co-crystallization studies of PDE-inhibitor complexes suggest that inhibitors may interact with the invariant glutamine at the active site. Inhibitors bind in a common subpocket which contains structural elements responsible for nonselective binding of inhibitors and for the hydrolysis of cAMP and cGMP, as well as family-specific sequences responsible for differences in substrate affinities and sensitivities to family-specific inhibitors, such as IC224 and IC295 (PDE1); EHNA (erythro-9-(2 hydroxy-3-nonyl)-adenine) and BAY60-7750 (PDE2); milrinone, cilostazol, and cilostamide (PDE3); rolipram and roflumilast (PDE4); sildenafil, vardenafil, and tadalafil (PDE5).

Regulatory Domain

N-terminal portions of PDE molecules are highly divergent, containing structural determinants and specific amino acid sequences that allow different PDEs to respond selectively to specific regulatory signals, and to interact and communicate with the surrounding cellular milieu (Figure 1). These regulatory regions include dimerization domains and autoinhibitory modules (e.g., in PDEs 1, 4, and 5), as well as sites and domains that are subject to different types of covalent modification (e.g., sites in PDEs 1, 3, 4, 5, 10, and 11 for phosphorylation by various protein kinases), or sites that interact with allosteric ligands (e.g., cGMP-binding sites in GAF domains), specific effectors (e.g., Ca²⁺/calmodulin), protein partners or molecular scaffolds (e.g., A kinase anchoring protein scaffolding proteins (AKAPs), β -arrestin, and caveolin), and thereby regulate catalytic activity, protein–protein interactions, and/or subcellular compartmentation and localization (Figure 1). Five PDE families (PDEs 2, 5, 6, 10, and 11) contain homologous so-called GAF domains, an acronym for proteins (cGMP-binding PDEs, Anabena adenyl cyclase and *hflA*, an *Escherichia coli* transcriptional regulator) that contain these sequences. Although cGMP binding is not the primary function of GAF domains, in three PDE families

Figure 1 Common structural pattern for different phosphodiesterase (PDE) gene families.

(PDEs 2, 5, and 6), GAF domains bind cGMP with high affinity, but with different functional consequences. PDE8 isoforms contain PAS domains, an acronym for proteins (period clock protein, aryl hydrocarbon receptor nuclear translocator, and single-minded protein) that contain these sequences. In PDE4 isoforms, ligand binding to upstream conserved regions (UCRs) may induce profound conformational changes that allow interactions between the ligand-bound UCR and the catalytic site, resulting in allosteric modulation of catalytic activity.

PDE Functions

PDEs: Components of Spatially Organized Signaling Networks and Microdomains

PDEs are critical regulators of the generation, amplitude, duration, and termination of intracellular cyclic nucleotide signals. In addition to tight regulation of their concentrations and turnover, intracellular pools of cAMP and cGMP are also temporally, spatially, and functionally compartmentalized. In cardiac myocytes, for example, PGE₁ and catecholamines increase cAMP and activate PKA in different compartments, and cAMP diffusion is spatially restricted and regulated, at least in part, by PDEs. Newer techniques, for example, use of fluorescence-resonance energy transfer (FRET) and cyclic nucleotide biosensors, also suggest that PDEs play an important role in these spatially constrained microdomains, that is, discrete subcellular regions in which cyclic nucleotide gradients are generated, monitored, and regulated, and their signals and effects channeled, transduced, and modulated.

By virtue of their unique N-terminal regions, the multiple PDE4 N-terminal splice variants are ideally designed for intracellular targeting to different subcellular compartments, molecular scaffolds (including AKAPs, β -arrestin, RACK1 (receptor for activated protein kinase C 1), myomegalin, spectrin, disrupted in schizophrenia (DISC1)), and other interacting protein partners. In these complexes and signaling microdomains, PDE4 isoforms determine local cAMP gradients, and, together with sequestered PKA and EPAC partners, gate activation of spatially segregated, localized signaling pathways. The 'classical' molecular basis for compartmentalization of cAMP signaling involves anchoring of PKA isoforms at specific intracellular sites via A Kinase Anchoring Protein scaffolding proteins (AKAPs). These proteins organize formation of localized signaling modules/microdomains consisting of kinases, kinase substrates, phosphatases, PDE (especially PDE4) isoforms, and other proteins, including EPACs. AKAPs anchor PKA in close proximity to substrate targets, leading to phosphorylation of compartmentalized PKA substrates. These modules sense intracellular cAMP gradients and effectively compartmentalize activation of substrates and biological responses. In these microdomains, cAMP-induced activation of PKA also results in phosphorylation/activation of PDE4 isoforms associated with AKAPs, resulting in modulation and termination of cAMP signals, and return of PKA to its basal state. For example, in cardiac myocytes, PDE4 isoforms are associated with AKAP complexes thought to modulate effects of cAMP on L-type and ryanodine-sensitive Ca²⁺ channels (RyR2). By limiting β -adrenoreceptor (BAR) stimulation/phosphorylation of RyR2, PDE4 may protect against proposed pro-arrhythmogenic effects of hyper-phosphorylated RyR2.

This signaling microdomain or module may have clinical relevance to human heart failure, in that it has been suggested that, in some patients, decreased PDE4 in this AKAP-centered macromolecular complex may contribute to disease progression via chronic dysregulation of PKA activation of Ca²⁺ transport and development of arrhythmias. This information has raised theoretical concerns regarding chronic administration of PDE4 inhibitors to older patients with heart failure.

PDE4 isoforms, PKA, and other molecules also interact/associate with β -arrestins, which are scaffolding proteins located in the vicinity of plasma membranes (PMs) that interact with activated β receptors and are involved in coordination of β receptor signaling and trafficking. This targeting and effective concentrating of PKA and PDE4 in proximity to the activated β receptors not only reduces cAMP generation (via phosphorylation, uncoupling, and internalization of β receptors) but also enhances localized degradation of cAMP and desensitizes the complex with respect to further signaling via the β receptor and cAMP.

Experiments in isolated cardiomyocytes strongly suggest that specific PDEs are functionally coupled with discrete pools of adenylyl cyclase/G-protein-coupled receptors that respond to specific hormones. For example, β_1 AR-induced cAMP is regulated by PDE3 and PDE4, whereas glucagon R-induced cAMP is regulated by PDE4 alone. Although PDE2 accounts for a minor fraction of PDE activity in neonatal rat cardiomyocytes, it seems to be specifically involved in the hydrolysis of cAMP induced by β AR stimulation. Since PDE2 is stimulated by cGMP, it mediates inhibitory effects of cGMP on β AR-induced increases in cAMP and contractility.

The subcellular localization of different PDEs, their interactions with molecular scaffolds and interacting partners, and their inclusion in, and contribution to the function of, macromolecular signaling microdomains is becoming a common theme in PDE biology. In human platelets, PDE5, PKG1 β , and inositol-1,4, 5-triphosphate receptor type 1 (IP(3)R1) are integral components of a complex that regulate effects of cGMP on IP(3)R1-mediated Ca²⁺ release. In 3T3-L1 adipocytes, PDE3B is found in caveolin-enriched PM fractions, and endoplasmic reticulum (ER) and Golgi membrane fractions. Treatment of adipocytes with insulin resulted in phosphorylation/activation of PDE3B associated with internal membranes (ER/Golgi), whereas treatment with the β_3 -receptor agonist, CL316,243 (CL), resulted in phosphorylation/activation of PDE3B associated with PM/caveolae fractions. Activation of PDE3B by insulin and CL involves the reversible assembly of distinct macromolecular complexes that contain phosphorylated PDE3B and different sets of signaling effectors thought to be involved in activation of PDE3B by insulin or CL. Insulin- or CL-mediated macromolecular complex formation was significantly inhibited by caveolin-1 knockdown, suggesting that cav-1 acts as a molecular chaperone or scaffolding molecule in cholesterol-rich lipid rafts that may be necessary for the proper stabilization and activation of PDE3B in response to CL and insulin.

PDEs: Homeostatic Regulators

Signaling pathways, in general, also include mechanisms for negative feedback control. PDE3 and PDE4 activities, for

example, are acutely upregulated by cAMP-induced activation of PKA, which results in phosphorylation/activation of PDE3 and PDE4, and enhanced destruction of cAMP. This rapid destruction/turnover is crucial in the transient accumulation of intracellular cAMP that usually occurs in response to acute stimuli, and important in resetting cAMP homeostasis. Feedback regulation of cAMP destruction in cAMP-signaling microdomains described above maintains compartmentalized cAMP, and controls diffusion of cAMP signals. Chronic elevation of cAMP also provides negative feedback, by increasing transcription of PDE3 and PDE4 genes and protein synthesis, resulting in increased enzymatic activities. In some cells, this latter phenomenon is part of mechanisms involved in ligand-induced downregulation of cellular responses, such as tachyphylaxis or desensitization. Negative feedback control of cGMP hydrolysis by PDE5 is somewhat different, due to the presence of high-affinity, noncatalytic, allosteric-binding sites for cGMP in the GAF domains of PDE5. Binding of cGMP to GAF domains results in allosterically induced conformational changes that increase affinity of the catalytic site for cGMP and also facilitates phosphorylation and activation of PDE5 by PKG. Thus, elevation in intracellular cGMP provides negative feedback control and enhances its own destruction, via both direct cGMP-induced allosteric activation as well as indirect activation due to phosphorylation of PDE5 by PKG.

PDEs: Intracellular Effectors

PDEs not only are important determinants in the stringent regulation of intracellular cAMP and cGMP concentrations, but also serve as effectors of cyclic nucleotide actions. Historically, in cells containing multiple PDEs, family-specific PDE inhibitors were initially utilized to pharmacologically define roles of specific PDEs in regulating specific signaling pathways and discrete cellular functions. In cultured mammalian oocytes, PDE3 inhibitors, not PDE4 or 5 inhibitors, inhibit meiotic progression and oocyte maturation, implying that PDE3 regulates a cAMP pool that controls maturation. (In fact, female PDE3A knockout (KO) mice are sterile.) In cultured renal mesangial cells, experiments with PDE3 and PDE4 inhibitors indicated that PDE3 and PDE4 selectively regulated functionally distinct cAMP pools that controlled cell growth and generation of reactive oxygen species, respectively. These types of studies first suggested a role for PDEs in spatial and/or functional compartmentalization of cyclic nucleotide signals and effects.

In some instances, a specific PDE serves as a crucial effector system and regulates a unique cellular function, for example, in retinal rods and cones, light-induced activation of photoreceptor PDE6 results in hydrolysis of cGMP and initiation of visual signal transduction. Activation of PDE3s by insulin, IGF-1, and leptin is apparently important in their ability to reduce cAMP and thereby regulate lipolysis in adipocytes, glycogenolysis in hepatocytes, insulin secretion from pancreatic β cells, and oocyte maturation. In these instances, PDE3 inhibitors can attenuate or block the effects of insulin, IGF-1, and leptin. In monocytes/macrophages, upregulation of a specific PDE4B splice variant is required to relieve cAMP inhibition of tumor necrosis factor (TNF) production and toll-like receptor signaling.

Studies of PDE KO mice do indicate that the ability of specific PDEs to regulate discrete cAMP/cGMP signaling pathways and actions is genetically determined. Female PDE3A KO mice are sterile, most likely due to inhibitory effects of cAMP on meiotic progression and maturation of oocytes and, consequently, their competency for fertilization. PDE3B KO mice, not frankly diabetic, demonstrate signs of disruption in insulin secretion and insulin resistance. Compared with wild-type (WT) mice, PDE3B KO mice and PDE4B KO mice were leaner, with lower fat pad weights and smaller adipocytes, and with reduced inflammation and macrophage markers in white adipose tissue (WAT). PDE3B KO WAT exhibited phenotypic characteristics of brown adipose tissue. These data suggest a role for both PDE3 and PDE4 in regulation of energy homeostasis, and are of particular interest, because some of the beneficial metabolic effects of the polyphenol resveratrol, at least in rodents, may be mediated by inhibition of PDE3 and PDE4. Production of TNF α in response to administration of lipopolysaccharide (LPS) in PDE4B KO mice is profoundly (~90%) inhibited. On the other hand, PDE4D KO mice do not exhibit acetylcholine-induced contraction and hyper-reactivity of airway smooth muscle. In PDE4D KO mice, the duration of β -adrenergic-induced anesthesia is reduced by more than 50%, and fertility is decreased due to reduced ovulation. Targeted inactivation of PDE1B alters locomotion activity, whereas sperm function is impaired in PDE11 KO mice.

PDEs: Signal Integrators

With their different intrinsic properties and different responses to regulatory signals, PDEs also integrate multiple inputs and are a locus for cross-talk between different signaling pathways. For example, PDE2, which is allosterically activated by cGMP, is highly concentrated in adrenal zona glomerulosa cells. In these cells, atrial natriuretic factor (ANF) increases cGMP synthesis; cGMP, in turn, activates PDE2, leading to a decrease in cAMP and PKA activity and inhibition of cAMP-stimulated aldosterone production. On the other hand, in other cells, NO activates guanylyl cyclase and increases cGMP, which inhibits PDE3 and increases intracellular cAMP content, resulting, for example, in stimulation of renin secretion from the juxtaglomerular apparatus in the kidney and inhibition of platelet aggregation.

Human platelets offer an excellent example of signal integration by PDE2, PDE3, and PDE5. At low cAMP, PDE3 is important and is inhibited by endogenous cGMP, produced by nitrovasodilator-activation of guanylyl cyclase or by inhibition of the cGMP-specific PDE5. This inhibition of PDE3 results in increased cAMP and inhibition of platelet aggregation. At higher cGMP (or cAMP) concentrations, PDE2 is allosterically activated to hydrolyze cAMP. Thus, activation of PDE2 limits accumulation of cAMP in platelets and aids in maintenance of cAMP homeostasis.

Newer approaches have suggested that different PDE isoforms may not only coordinate regulation of signals and responses in individual cells, but that differential cellular distribution within tissues may be important in intercellular communication and regulation of tissue function. Immunohistochemical studies indicate, for example, that PDE1C and PDE2A are expressed in different sets of neurons in the olfactory epithelium, whereas PDE1C

and PDE4A are present in different subcellular regions of the same neurons. In certain cells, for example, pancreatic beta-cells and olfactory epithelium, Ca^{2+} /calmodulin regulation of PDE1, together with adenylyl cyclases 1 and 8, allow coupling of cAMP and Ca^{2+} oscillations, crucial for rapid functional responses in these cells.

Inherited Diseases Associated with PDEs

At present, mutations in the PDE6 and PDE11 genes represent the clearest examples of association of PDE mutations with human disease. Recessive mutations in rod PDE6B have been found in 5–6% of patients with retinal degeneration; mutations in PDE6A are associated with autosomal recessive retinitis pigmentosa. Mutations in PDE11A gene have been found in a subgroup of patients presenting with bilateral adrenal hyperplasia and Cushing's syndrome. Although controversial and not replicated in all studies, there have been reports correlating PDE4D haplotypes and single-nucleotide polymorphisms and stroke, and perhaps, PDE4B and schizophrenia.

Family-Specific Inhibitors: Clinical Applications

Molecular diversity of PDEs has occasioned the development of family-specific PDE inhibitors to replace nonselective PDE inhibitors (theophylline and caffeine) as therapeutic agents for a wide variety of major diseases. PDE5 inhibitors, especially Viagra®, Levitra®, and Cialis®, have been very successful in the treatment of erectile dysfunction, and are approved by the FDA for pulmonary hypertension. The PDE3 inhibitor Pletal® is used to alleviate symptoms in a type of peripheral vascular disease, that is, intermittent claudication. PDE3 inhibitors, which enhance myocardial contractility and relaxation of smooth muscle and inhibit platelet aggregation, failed in long-term clinical trials for the treatment of chronic heart failure, but one PDE3 inhibitor, milrinone, is approved for acute and short-term treatment of adult patients with decompensated and refractory cardiac failure. PDE4 enzymes are relatively highly concentrated in immune/inflammatory cells, and specific PDE4 inhibitors exhibit potent anti-inflammatory actions. For these reasons, selective PDE4 inhibitors, targeted toward the active catalytic site, have been extensively studied as anti-inflammatory drugs for treatment of asthma and chronic obstructive pulmonary disease (COPD), and also (on a smaller scale) as possible therapeutic agents for rheumatoid arthritis, multiple sclerosis, type II diabetes, septic shock, atopic dermatitis and other autoimmune diseases, and depression. Virtually, all clinical trials with PDE4 inhibitors, however, have not been successful, because tolerability problems, especially emesis and diarrhea, have precluded achievement and maintenance of clinically effective concentrations. A novel strategy has recently been initiated in the development of PDE4D inhibitors that may allow these drugs to achieve their rich and highly anticipated therapeutic promise. This new class, termed 'allosteric modulators', which limit access of substrate to the PDE4D active site, are apparently potent in pre-clinical assays, but have much less potential for emesis than existing PDE4 inhibitors.

Conclusions

By virtue of their distinct intrinsic characteristics and differential regulation, their intracellular targeting to different subcellular locations and microdomains, and their interactions with cellular structural elements, regulatory partners, and molecular scaffolds such as AKAPs, β arrestin, and caveolin, different PDEs can integrate multiple cellular inputs and modulate the intracellular diffusion and functional compartmentalization of cyclic nucleotide signals. The combined enormous molecular diversity of receptors and their ligands, adenylyl and guanylyl cyclase systems, PDEs, and cyclic-nucleotide-regulated effector systems, coupled with their physical and functional compartmentalization, provides for the complex integration, specificity, and variety of networks and pathways involved in generation, transduction, modulation, and termination of cyclic-nucleotide-gated signals and actions. The ability of scaffolding proteins to spatially organize signaling molecules, including protein kinases, phosphatases, kinase substrates, PDEs, and other signaling and effector molecules, effectively allows cells to generate signaling specificity by using small, discrete, and spatially segregated subsets of proteins which exhibit overlapping or redundant functions. Integration of these myriad combinations establishes the unique cyclic nucleotide networks and phenotypes that characterize individual cells.

Glossary

Channel states Voltage-gated channels have at least three states: a closed, an open, and an inactivated state. Ions pass the channel at the open state.

Ligand-gated channel In contrast to voltage-gated channels, ligand-gated channels are opened by the occupation of the ligand-binding site. Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are gated by the membrane potential and are modulated

by the binding of cyclic adenosine monophosphate (cAMP).

Olfaction The processing of smell in the nose and olfactory bulb.

Pacemaker cells Specialized cells that depolarize at a known frequency. The best-known example is the sinoatrial node cells of the heart.

Photoreceptors Light-sensitive neurons (rods and cones) of the retina that confer vision.

Introduction

Cyclic nucleotides exert their physiological effects by binding to four major classes of cellular receptors: cyclic adenosine monophosphate (cAMP)- and cyclic guanosine monophosphate (cGMP)-dependent protein kinases, cyclic GMP-regulated phosphodiesterases, cAMP-binding guanine nucleotide exchange factors, and cyclic nucleotide-regulated cation channels. Cyclic nucleotide-regulated cation channels are unique among these receptors because their activation is directly coupled to the influx of extracellular cations into the cytoplasm and to the depolarization of the plasma membrane. Two families of channels regulated by cyclic nucleotides have been identified, the cyclic nucleotide-gated (CNG) channels and the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. The two channel classes differ from each other with regard to their mode of activation. CNG channels are opened by direct binding of cAMP or cGMP. By contrast, HCN channels are principally operated by voltage. These channels open at hyperpolarized membrane potentials and close on depolarization. Apart from their voltage sensitivity, HCN channels are also activated directly by cyclic nucleotides, which act by increasing the channel open probability.

General Features of Cyclic Nucleotide-Regulated Cation Channels

Structurally, both CNG and HCN channels are members of the superfamily of pore loop cation channels. Like other subunits encoded by this large gene family, CNG and HCN channel subunits assemble to tetrameric complexes. The proposed structure and the phylogenetic relationship of mammalian CNG and HCN channel subunits are shown in [Figure 1](#). The transmembrane channel core consists of six α -helical segments (S1–S6) and an ion-conducting pore loop between the S5 and S6. The amino- and carboxy-termini are localized in the cytosol. CNG and HCN channels contain a positively charged S4 helix carrying three to nine regularly spaced

arginine or lysine residues at every third position. In HCN channels, as in other voltage-operated members of the channel superfamily, the S4 helix functions as a voltage-sensor conferring voltage-dependent gating. In CNG channels, which are not gated by voltage, the specific role of S4 is not known.

CNG and HCN channels reveal different ion selectivities. CNG channels conduct both Ca^{2+} and monovalent cations with permeability ratios $P_{\text{Ca}}/P_{\text{Na}}$ ranging from about 2 to 25 depending on the respective channel type and the cyclic nucleotide concentration. By providing an entry pathway for Ca^{2+} , CNG channels control a variety of cellular processes that are triggered by this cation. Under physiological conditions, HCN channels pass Na^+ and K^+ ion with a relative permeability ratio $P_{\text{Na}}/P_{\text{K}}$ of about 0.15–0.25. In addition, there is recent evidence for a small but significant Ca^{2+} permeability of these channels. The functional relevance of Ca^{2+} entry through HCN channels is not clear at the moment.

In the carboxy-terminus, CNG and HCN channels contain a cyclic nucleotide-binding domain (CNBD) that has significant sequence similarity to the CNBDs of most other types of cyclic nucleotide receptors. In CNG channels, the binding of cyclic nucleotides to the CNBD initiates a sequence of allosteric transitions that lead to the opening of the ion-conducting pore. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage dependence of channel activation to more positive membrane potentials and thereby facilitate voltage-dependent channel activation. Despite the fact that the CNBDs of HCN and CNG channels show significant sequence homology, the two channel classes reveal different selectivities for cyclic nucleotides. HCN channels display an approximately 10-fold higher affinity for cAMP than for cGMP, whereas CNG channels select cGMP over cAMP.

CNG Channels

CNG channels are expressed in retinal photoreceptors and olfactory neurons and they play a key role in visual and

Figure 1 Phylogenetic tree and structural model of cyclic nucleotide-regulated cation channels. The cyclic nucleotide-gated (CNG) channel family comprises six members, which are classified into A subunits (CNGA1–4) and B subunits (CNGB1 and CNGB3). The hyperpolarization-activated cyclic nucleotide-gated (HCN) channel family comprises four members (HCN1–4). CNG and HCN channels share a common transmembrane topology, consisting of six transmembrane segments (1–6), a pore loop, and a cyclic nucleotide-binding domain (CNBD). CNG channels are activated *in vivo* by binding of either cAMP (cA) or cGMP (cG), depending on the channel type. HCN channels activate on membrane hyperpolarization (ΔV) and are enhanced by binding of cAMP. Structures involved in channel gating are shown in red. The positively charged amino acid residues in the S4 segment of HCN channels are indicated by (+). CL denotes the C-linker involved in activation gating of CNG and HCN channels.

olfactory signal transduction. CNG channels are also found at low density in some other cell types and tissues such as brain, testis, and kidney. Although the function of CNG channels in sensory neurons has been unequivocally demonstrated, the role of these channels in other cell types remains to be established. Based on phylogenetic relationship, the six CNG channels identified in mammals are divided into two subfamilies, the A subunits (CNGA1–4) and the B subunits (CNGB1 and CNGB3) (Figure 1). CNG channel A subunits (with the exception of CNGA4) can form functional homomeric channels in various heterologous expression systems. By contrast, B subunits do not give rise to functional channels when expressed alone. However, together with CNGA1–3, they confer novel properties (e.g., single-channel flickering, increased sensitivity for cAMP, and *L-cis*-diltiazem) that are characteristic of native CNG channels. The physiological role and subunit composition is known for three native CNG channels: the rod photoreceptor channel, the cone photoreceptor channel, and the olfactory channel. The CNG channel of rod photoreceptors is a tetramer composed of three CNGA1 and one long isoform of the CNGB1 subunit (CNGB1a). The cone photoreceptor channel consists of two copies of the CNGA3 and the CNGB3 subunit, respectively. CNG channels control the membrane potential and the calcium concentration of photoreceptors. In the dark, both channels are maintained in the open state by a high concentration of cGMP. The resulting influx of Na^+ and Ca^{2+} (dark current) depolarizes the photoreceptor and

promotes synaptic transmission. Light-induced hydrolysis of cGMP leads to the closure of the CNG channel. As a result, the photoreceptor hyperpolarizes and shuts off synaptic glutamate release. Mutations in CNG channel genes have been linked to retinal diseases. Mutations in the CNGA and CNGB1 subunits have been identified in the genome of patients suffering from retinitis pigmentosa. The functional loss of either the CNGA3 or the CNGB3 subunit causes total color blindness (achromatopsia) and degeneration of cone photoreceptors.

The CNG channel expressed in cilia of olfactory neurons consists of three different subunits: CNGA2, CNGA4, and a short isoform of the CNGB1 subunit (CNGB1b). The channel is activated *in vivo* by cAMP that is synthesized in response to the binding of odorants to their cognate receptors. The olfactory CNG channel is thought to conduct almost exclusively Ca^{2+} under physiological ionic conditions. The resulting increase in cellular Ca^{2+} activates a Ca^{2+} -activated Cl^- channel that further depolarizes the cell membrane. Ca^{2+} not only is a permeating ion of the olfactory CNG channel, but also represents an important modulator of this channel. CNG channels are desensitized by Ca^{2+} -calmodulin (CaM)-mediated feedback inhibition, which lowers the cAMP sensitivity. Although all three olfactory CNG channel subunits contain CaM-binding sites, only the binding site present in the CNGB1b subunit renders the channel sensitive to CaM. Unlike originally proposed, CaM-mediated CNG channel desensitization is not necessary for adaptation to repeated odorant exposure but rather acts as a termination mechanism for shaping responses of olfactory neurons during and after odorant stimulation.

HCN Channels

A cation current that is slowly activated by membrane hyperpolarization (termed I_h , I_f , or I_q) is found in a variety of excitable cells including neurons, cardiac pacemaker cells, and photoreceptors. The best understood function of I_h is the control of heart rate and rhythm by acting as pacemaker current in the sinoatrial (SA) node. I_h is activated during the membrane hyperpolarization following the termination of an action potential and provides an inward Na^+ current that slowly depolarizes the plasma membrane. Sympathetic stimulation of SA node cells raises cAMP levels and increases I_h by a positive shift of the current activation curve, thus accelerating diastolic depolarization and heart rate. Stimulation of muscarinic receptors slows down heart rate by the opposite action. In the brain, I_h fulfills diverse basic functions including control of neuronal rhythmicity, determination of resting membrane potential, dendritic integration, and synaptic plasticity.

HCN channels represent the molecular correlate of I_h . In mammals, the HCN channel family comprises four members (HCN1–4) that share about 60% sequence identity to each other and about 25% sequence identity to CNG channels. The highest degree of sequence homology between HCN and CNG channels is found in the CNBD. When expressed in heterologous systems, HCN channels generate currents displaying the typical features of native I_h : (1) activation by membrane hyperpolarization, (2) permeation of Na^+ and K^+ , (3) positive shift of the voltage dependence of channel activation by direct binding of cAMP, and (4) channel blockade by

extracellular Cs^+ . HCN1–4 mainly differ from each other with regard to their speed of activation and the extent by which they are modulated by cAMP. HCN1 is the fastest channel, followed by HCN2, HCN3, and HCN4. Unlike HCN2 and HCN4, whose activation curves are shifted by about +15 mV by cAMP, HCN1 and HCN3 are only weakly, if at all, affected by cAMP. Determination of the crystal structure of the CNBD combined with site-directed mutagenesis has provided insight into the complex mechanism underlying dual HCN channel activation by voltage and cAMP. Surprisingly, the voltage-dependent movement of the positively charged S4 helix is fully conserved between HCN channels and depolarization-activated channels such as Shaker K-channels. However, the allosteric coupling between S4 movement and the activation gate is different in the two channel types. In HCN channels, inward movement of S4 leads to the opening of the channel gate, whereas it closes Shaker K-channels. Major determinants affecting channel activation are the intracellular S4–S5 loop, the S5–P linker, the S1 segment, and the extracellular S1–S2 loop. The CNBD fulfills the role of an autoinhibitory channel domain. In the absence of cAMP, the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel core and thereby shifts the activation curve to more hyperpolarizing voltages. Binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal gating. It remains to be determined if the inhibitory effect of the CNBD is conferred by a direct physical interaction with the channel core domain or by some indirect pathway. There is evidence that the so-called C-linker, a peptide of about 80 amino acids that connects the last transmembrane helix (S6) to the CNBD, plays an important role in this process (Figure 1). The C-linker was also shown to play a key role in the gating of CNG channels, suggesting that the functional role of this domain has been conserved during channel evolution. The functional properties of HCN channels may also be influenced by auxiliary subunits such as MiRP1 or Trip8b.

HCN channels are found in neurons and heart cells. In brain, all four HCN channel isoforms have been detected with HCN2 being the most abundant isoform. By contrast, HCN1, HCN3, and HCN4 are enriched in specific regions of the brain such as thalamus (HCN4), hippocampus (HCN1), or olfactory bulb and hypothalamus (HCN3). HCN channels have also been detected in the retina and some peripheral neurons such as dorsal root ganglion neurons. In SA node cells, HCN4 represents the predominantly expressed HCN channel isoform. In addition, low amounts of HCN1 and HCN2 are also present in these cells. Insights into the (patho)physiological relevance of HCN channels have been gained from the analysis of mouse lines lacking individual HCN channel isoforms. Disruption of HCN1 impairs motor learning but enhances spatial learning and memory. Deletion of HCN2 results in absence epilepsy, ataxia, and sinus node dysfunction. Mice lacking HCN4 die *in utero* because of the failure to generate mature SA pacemaker cells. By contrast, mice in which HCN4 is

deleted in adult stage are viable but display cardiac arrhythmia characterized by recurrent sinus pauses. The key role of HCN4 in controlling heart rhythmicity is corroborated by genetic data from human patients. Mutations in the human HCN4 gene, leading to mutated or truncated channel proteins, have been found to be associated with sinus bradycardia and complex cardiac arrhythmia.

Glossary

Endocytosis The taking in, by a cell, of soluble or membrane-bound material from outside the cell.

In the case of eukaryotic cells, endocytosed material passes into the endosome, a membrane-limited organelle that can fuse with lysosomes to allow digestion of the contents.

Homeostasis The normal balance of a healthy living organism, in which the status quo is maintained by regulatory mechanisms such as feedback control. In protein turnover, it is the balance between protein synthesis and protein breakdown.

Hydrolase An enzyme that breaks peptide, ester, or glycoside bonds by the addition of water. In the case of proteases, water is split, and the resulting oxygen is added to the newly formed carboxyl terminus while the two

hydrogens are added to the new amino terminus formed by the breaking of the peptide bond.

Protease An enzyme that cleaves proteins or peptides (also called proteinase, peptidase, or proteolytic enzyme).

Specificity Susceptibility of an amino acid sequence of a peptide or protein to cleavage by a particular protease. Most proteases possess specificity for the cleavage of particular sequences. For instance, caspases cleave immediately after aspartic acid residues (they cleave aspartyl bonds); most lysosomal cysteine proteases cleave the second peptide bond on the carboxyl side of a hydrophobic residue, the exception being legumain, which cleaves asparaginyl bonds. Specificity is conferred by the structure of the substrate-binding groove on the protease.

Phylogenetic Relationships

The use of the cysteine residue thiolate ion as the nucleophile for peptide-bond cleavage appears to have been derived at least 5 times during evolution using different structural frameworks, and members of each of these protease families are widely distributed. However, the bulk of these enzymes are members of clans CA and CD as classified in the MEROPS database (a regularly updated and invaluable source of information on proteases) (Figure 1). Clan CA contains the earliest identified cysteine proteases, such as the papaya protease papain, and the mammalian proteases, for example, cathepsins B, L, S, and K. These enzymes are generally present in lysosomes or in other membrane-bound compartments where they mediate antigen processing and presentation, or they are secreted from the cell. As a group, clan CA proteases show cleavage selectivity for the residue 2 positions N-terminal to the cleavage site. A related subfamily of papain-like enzymes is the calcium-dependent calpains, which are found in the cytoplasm and mediate various intracellular processes.

The second major group of cysteine proteases, clan CD, has been described much more recently and includes the caspases, legumains, several viral proteases, and separase, which is responsible for the separation of sister chromatids during mitosis. Unlike the papain family, these proteases generally show exquisite specificity for cleavage C-terminal to particular amino acid residues – aspartic acid in the case of caspases, asparagine for legumains, and arginine for separase. The caspases are the mediators of apoptosis.

Mechanism

Proteolytic enzymes are very efficient catalysts that can increase the rate of peptide-bond hydrolysis a billionfold. In the case of the cysteine proteases, the catalytic mechanism has been most extensively investigated for the clan CA enzymes. Despite their distinct evolutionary origins, it appears that the mechanism of other cysteine proteases is quite similar (an example of convergent evolution). Cleavage of the peptide bond depends on a thiolate–imidazolium ion pair provided by the cysteine and histidine residues in the active site (Figure 2). The environment of the active site results in an unusually low acid dissociation constant (pK_a) of around 4 for the cysteine thiol group. Nucleophilic attack on the carbonyl group results in the formation of a tetrahedral oxyanion intermediate. This then accepts a proton from the imidazolium group, resulting in the formation of an acyl enzyme intermediate and the release of the C-terminal portion of the substrate. In a second reaction, the acyl enzyme intermediate is deacylated by a water molecule and the remaining portion of the substrate is released.

Control

Activation

As is the case with most proteolytic enzymes, cysteine proteases are synthesized as inactive precursors, allowing them to be delivered to their intended site of action without harming the biosynthetic machinery of the cell. Often these proenzymes are

retained in an inactive form until their services are required. Very different strategies have evolved for the activation of the precursors of the different cysteine protease groups. In the case of the papain family, an N-terminal propeptide blocks access to the fully functional active site by binding in the reverse orientation to that required for peptide-bond cleavage (Figure 1). Its removal via inter- or intramolecular proteolysis liberates the functional protease. In contrast, the caspases undergo dimerization, which signals a rearrangement of the protein to form the previously incomplete active site.

Figure 1 Cysteine protease structure. Ribbon diagrams of representative members of the two principal cysteine peptidase clans: (a) cathepsin K (pdb 1by8), a member of the papain family in clan CA shown as the proenzyme, and (b) caspase-3 (pdb 1cp3), a member of clan CD. The active site cysteine and histidine residues are shown in ball and stick representation. For caspase-3, the position occupied by the substrate is indicated by the green rod. For procathepsin K, the proregion is depicted in green. The extended coil linking the helical region of the propeptide passes through the active site in the region normally occupied by the substrate. Processing of the proforms of papain family members requires the proteolytic removal of the proregion without any change to the structure of the protease component. In contrast, major restructuring of the active site occurs during caspase activation and the active form of the enzyme is a dimer of the structure shown.

Inhibitors

A further level of control for unwanted proteolytic activity is provided by the action of a series of cysteine protease inhibitors. Members of the cystatin family are highly effective inhibitors of papain-like enzymes. The N-terminus of the cystatin molecule binds in the active site cleft in a substrate-like manner, but the inhibitor evades cleavage by the target protease due to the presence of a glycine residue at what would normally be the site of cleavage. Additional elements in the inhibitor bind to the protease to maneuver the N-terminal substrate region just out of the range of the catalytic residues. A separate family of inhibitors, termed inhibitors of apoptosis proteins (IAPs), is available for the caspases. These proteins bind across the active caspase, obstructing normal substrate access but making limited interactions with the protease. Analogous to the propeptides of the papain family members, IAPs ensure their resistance to proteolysis by binding in the reverse direction to that required for substrate cleavage.

Physiology

Lysosomal Proteolysis

Virtually, all eukaryotic cells possess membrane-enclosed organelles known as lysosomes. This structure is the site of breakdown of endocytosed or phagocytosed material, and it is also the location for the turnover of certain cytosolic proteins and organelles. In most eukaryotic cells, the lysosome has the highest concentration of cysteine proteases and other hydrolases, which implies that these enzymes are involved in protein degradation for the recycling of amino acids for protein synthesis. This is indeed likely to be the major physiological function of ubiquitously expressed cysteine proteases such as cathepsin L, legumain, cathepsin B, and cathepsin H. Indeed, the last two enzymes, which fragment polypeptides (endopeptidase action) and then attack the fragments either at the C-terminal end, in the case of cathepsin B (carboxypeptidase

Figure 2 Cysteine protease mechanism. Scheme for the reaction mechanism of cysteine protease action. The active-site cysteine and histidine residues are present as a thiolate (S^-)-imidazolium (ImH^+) ion pair. The substrate is represented by the carbonyl group under attack connected to the N-terminal peptide component R and the C-terminal component X. Upon substrate binding, nucleophilic attack by the thiolate ion results in the formation of a tetrahedral oxyanion intermediate. This, following proton donation from ImH^+ , breaks down to form an acyl enzyme (thiol ester) intermediate with the release of the C-terminal fragment HX. Adapted from Polgár L and Asbóth B (1986) The basic difference in catalysis by serine and cysteine proteinases resides in charge stabilization in the transition state. *Journal of Theoretical Biology* 121: 323–326.

action), or at the amino terminus, in the case of cathepsin H (aminopeptidase action), are functionally well equipped to fulfill a digestive role.

Antigen-Ii Processing

In the major histocompatibility complex (MHC), class II antigen-presenting cells, such as dendritic cells, macrophages, and B lymphocytes, the lysosomal or endocytic localization of some cysteine proteases has allowed them to participate in antigen presentation to T cells. In this process, the antigen is endocytosed and fragmented into peptides of between 13 and 26 amino acids in length. In order to allow the peptides thus generated to bind to the MHC complexes for presentation at the cell surface, the invariant chain Ii must be cleaved in order to remove it from the peptide-binding groove. Cathepsin S has been known for some time to be highly expressed in antigen-presenting cells, and recently the use of selective cathepsin S inhibitors and the generation of cathepsin S-null mice have demonstrated an important, but not solitary, role for this enzyme in Ii processing.

It is likely that a number of endosomal proteases are involved in antigen processing and also that the protease involved depends on the nature of the antigen. In some cases at least, legumain appears to play an important role.

Bone Turnover

Bone is continually being broken down and replenished. This is important in calcium homeostasis, in which soluble calcium is provided by the hydrolysis of the mineral fraction of bone. At the same time, the organic component of bone, consisting largely of type I collagen, is also removed. Although a normal physiological process, under some circumstances bone resorption can outstrip synthesis. This can lead to the condition known as osteoporosis or brittle bone disease, which largely affects postmenopausal women. Other situations in which bone resorption is outside normal homeostatic control include bone metastases and some rare genetic diseases. The process of bone resorption is mediated largely by the multinucleated cell type known as an osteoclast. During periods of active resorption, osteoclasts sitting on bone surfaces generate a ruffled membrane, effectively sealing off the area immediately beneath the cell into which proteolytic enzymes and acid are secreted to remove the organic and mineral components, respectively. Both cysteine proteases and matrix metalloproteinases have been implicated in the hydrolysis of the organic component of bone, and it is likely that the relative contributions played by these different enzymes depend on the type of bone, with cysteine proteases playing a dominant role in the resorption of long bone.

The discovery that pycnodysostosis, an autosomal recessive disease leading to short stature and bone fragility, was due to the deficiency in cathepsin K activity, provided the first indication that this cysteine protease played a major role in bone resorption. Laboratory experiments have demonstrated this enzyme's efficiency at cleaving type I collagen, and consequently it has become a major drug target for the treatment of bone-resorbing diseases.

Other cysteine proteases are likely to be involved in bone resorption. For instance, legumain acts as an inhibitor of bone resorption by inhibiting the formation of multinucleated osteoclasts from their mononuclear precursors. The precise mechanism is not known, but it is not linked to the catalytic activity of the enzyme, and in fact the active component is the C-terminal peptide that is removed upon generation of full catalytic activity.

Thyroglobulin Processing

The distribution of cathepsin K is quite restricted, being found predominantly in the ovary and osteoclasts, the bone-degrading cells. The other site where cathepsin K is highly expressed, alongside the more ubiquitously distributed cathepsins B and L, is in the thyroid follicles, which are the site of storage of thyroglobulin, the precursor of the thyroid hormones. It appears from experiments using single- and double-knockout mice that all three of these cysteine proteases are involved in thyroid hormone generation from thyroglobulin. All are found in the lumen of thyroid follicles, where cathepsin L appears to be involved in both the solubilization of cross-linked thyroglobulin and the subsequent generation of thyroid hormones. In contrast, cathepsin B may be primarily involved in thyroglobulin solubilization and cathepsin K in thyroid hormone generation.

Apoptosis

The importance of programmed cell death to developmental processes has been recognized for many years. The discovery that the proapoptotic *ced-3* gene of *Caenorhabditis elegans* encodes a protease homologous to the mammalian cysteine protease interleukin-1 β -converting enzyme (ICE), together with the demonstration that ICE induces apoptosis in mammals, ignited a great deal of renewed interest in the field, due, in large part, to the desire of the pharmaceutical industry to control the process. This article is too short to do justice to such a large area of research, which has been the subject of a number of good reviews. Briefly, the proteases most intricately involved in the process of apoptosis are the caspases (including ICE), all of which have acute specificity for the cleavage of aspartyl bonds and which function in a cascade reaction. Upstream caspases activate downstream caspases, which cleave proteins whose functions are essential to cell survival. One of the initiators of this cascade event is the occupation of cell surface death receptors of the tumor necrosis factor receptor 1 family, which triggers the activation of caspase 8. Alternatively, the formation of a complex with cytochrome c and Apaf-1 in response to DNA damage leads to the activation of caspase 9. Both of these initiating caspases then activate the downstream executioner caspases, such as caspase 3. In cell killing by cytotoxic T cells or natural killer (NK) cells, this pathway is hijacked in the target cell through the ability of the killing cell's serine proteinase, granzyme B, to activate caspases.

It has become increasingly clear that, under some circumstances, cysteine proteases other than caspases are involved in apoptosis. For instance, cathepsin B may be involved in death receptor-mediated apoptosis of tumor cells if downstream

caspases are inhibited. This process is expedited by tumor necrosis factor- and caspase 8-induced increases in cytosolic cathepsin B and subsequent release from mitochondria of cytochrome c.

Pathology

Cysteine proteases have been implicated in a wide range of pathologies, including cancer, osteoporosis, and arthritis. Here, we focus on their involvement in two other pathological situations that may be less fully appreciated.

Allergenic Proteinases

Proteases represent a disproportionately high number of allergens. Examples include the major allergen from the house dust mite (a cysteine protease that is the product of the *Der p1* gene) and many plant cysteine proteases such as actinidain, bromelain, papain, and glycyI endopeptidase. The normal route for the generation of atopy involves the initiation of a Th2 lymphocyte phenotype and enhanced IgE responses by B cells. Although the mechanisms by which cysteine (and other) proteases favor a switch to a Th2-like response are not completely elucidated, a link with the catalytic activity of these enzymes has been made. The mechanisms may be many and varied and include the cleavage (and activation?) of IgE and IL-2 receptors and disruption of epithelial tight junctions, thus enhancing access by allergens to immune cells. However, a systematic analysis of potential molecular targets for these enzymes has not been undertaken.

Parasitic Proteinases

Many parasites contain cysteine proteases in their phagocytic vacuoles, where they are involved in the digestion of engulfed material to be used in satisfying the nutritional requirements of the organism. As such, these enzymes are potential therapeutic targets. Examples include *Entamoeba histolytica*, a causative agent of amebic dysentery; trypanosomatids that cause

African sleeping sickness and Chagas' disease; schistosomal organisms and the plasmodial parasites that are the causative agents of malaria; and a number of parasitic helminths. In the case of plasmodial parasites, the cysteine proteases are known to be instrumental in the degradation of host hemoglobin, the principal source of amino acids for the parasite, because enzyme inhibition blocks hemoglobin degradation and parasite development. In a mouse model of the human disease, an orally administered inhibitor of the enzyme produced a 40% cure rate, and a delayed progression of the disease in the remaining animals. New treatments for this and other parasitic diseases that kill millions every year are badly needed, due to the increasing resistance to currently available drugs.

Glossary

Protonmotive Q cycle The mechanism of electron transfer by which the cytochrome *bc*₁ complex transfers electrons from ubiquinol to cytochrome *c* and links the electron transfer to proton translocation. The mechanism is so named because the enzyme oxidizes ubiquinol on one side of the membrane and re-reduces ubiquinone on the other side in a cyclic manner, thus bringing about transmembrane

movement of protons, carried through the membrane as hydrogen atoms on the quinol hydroxyl groups.

Ubiquinone 2,3-Dimethoxyl-5-multiprenyl-6-methyl-1,4-benzoquinone, where the multiprenyl group is an isoprenoid side chain consisting of 6–10 isoprenyl groups, is a lipid-soluble benzoquinone that is reduced to quinol by various dehydrogenases and reoxidized to quinone by the cytochrome *bc*₁ complex.

The cytochrome *bc*₁ complex (ubiquinol: cytochrome *c* oxidoreductase complex, E.C. 1.10.2.2) is an energy-transducing, electron-transfer enzyme located in the inner mitochondrial membrane of oxygen-utilizing eukaryotic cells, where it participates in cell respiration. A functionally similar but structurally simpler version of the *bc*₁ complex is located in the plasma membrane of many, but not all, bacteria, where it takes part in respiration, denitrification, nitrogen fixation, and cyclic photosynthetic electron transfer, depending on the species. In all of these organisms, the *bc*₁ complex oxidizes a membrane-localized quinol and reduces a water-soluble, *c*-type cytochrome and links this redox reaction to translocation of protons across the membrane in which the *bc*₁ complex resides. The *bc*₁ complexes from mitochondria of several species have been crystallized and the mechanism of the enzyme is generally well understood, although some questions remain outstanding.

Function of the *bc*₁ Complex

The cytochrome *bc*₁ complex participates in respiration in oxygen-utilizing cells and also participates in electron transfer in numerous bacteria that utilize alternative terminal-electron acceptors in addition to oxygen. The functional relationship of the *bc*₁ complex to other redox enzymes in these linked electron-transfer systems is illustrated in [Figure 1](#). In mitochondria the *bc*₁ complex is a confluence point for reducing equivalents from the various dehydrogenases and it is essential for mitochondrial respiration, as there is no alternative route to oxidize ubiquinol by molecular oxygen. Bacteria such as *Paracoccus denitrificans* that have a *bc*₁ complex usually have alternative mechanisms to oxidize ubiquinol or otherwise bypass the *bc*₁ complex. Consequently, the enzyme is not essential in these organisms. Hydroxyquinone analogs of ubiquinone, such as atovaquone, inhibit the *bc*₁ complex and are used therapeutically against fungal (e.g., pneumocystis) and parasitic (e.g., malaria) infections, but are ineffective against bacteria in which the enzyme is not essential. In some photosynthetic bacteria, such as *Rhodobacter*, the *bc*₁ complex is essential for cyclic photosynthetic electron transfer in the absence of a terminal electron acceptor, but is not essential when the cells are

growing heterotrophically. In all of these organisms, the *bc*₁ complex is located in the organelle or plasma membrane and converts the energy associated with electron transfer from ubiquinol to cytochrome *c* into an electrochemical proton gradient across the membrane in which the enzyme resides. The resulting protonmotive force is used by the cell for energy-requiring reactions, including adenosine triphosphate (ATP) synthesis, ion and metabolite transport, and flagellar motion.

Structure, Composition, and Properties of the *bc*₁ Complex

Protein Subunits

All cytochrome *bc*₁ complexes contain three protein subunits with redox prosthetic groups, a diheme cytochrome *b* containing a relatively high-potential *b*_H heme and a lower potential *b*_L heme, cytochrome *c*₁, and a Rieske iron–sulfur protein with a 2Fe–2S cluster. In some bacteria, such as *P. denitrificans* and *Rhodospirillum rubrum*, the *bc*₁ complex contains only these three subunits. Other bacteria, including the *Rhodobacter*, contain a fourth subunit of unknown function that lacks prosthetic groups. *Rhodobacter* can adapt to grow photosynthetically when this subunit is absent, but the stability of the enzyme is compromised, suggesting at least a structural role.

The cytochrome *bc*₁ complexes of mitochondria contain as many as seven or eight supernumerary subunits. The enzyme from *Saccharomyces cerevisiae* contains 10 subunits, while those from bovine heart and *Schizosaccharomyces pombe* contain 11. The difference between the 10- and 11-subunit enzymes is due to the fact that the 11-subunit enzymes contain one small subunit that is formed when the presequence that targets the Rieske protein to the mitochondria is cleaved from the protein. The cleaved presequence is retained in the *bc*₁ complex as an additional subunit. In *S. cerevisiae*, the presequence is cleaved from the Rieske protein in two steps and degraded, thus that *bc*₁ complex contains only 10 subunits.

The functions of the supernumerary subunits in the mitochondrial enzymes are not known. They are not required for the electron transfer and proton translocation activities of the enzyme, since the three-subunit enzyme from *Paracoccus*

Figure 1 Function of the cytochrome *bc*₁ complex in mitochondria and bacteria. In mitochondria, the *bc*₁ complex oxidizes ubiquinol that is formed by reduction of ubiquinone by various dehydrogenases including glycerol phosphate dehydrogenase, succinate dehydrogenase, NADH dehydrogenase, and ETF dehydrogenase. In bacteria, such as *Paracoccus denitrificans*, ubiquinol can be oxidized by various routes that bypass the *bc*₁ complex, including a terminal oxidase, cytochrome *o*, which oxidizes ubiquinol directly, without the intervention of cytochrome *c* and cytochrome *c* oxidase. These bacteria can also use alternative terminal electron acceptors, such as nitrate, in which case the *bc*₁ complex is also not essential for electron transfer from the quinol. In photosynthetic bacteria, such as the *Rhodobacter*, the *bc*₁ complex participates in cyclic electron transfer when the bacteria are grown photosynthetically, and is essential under those growth conditions. However, *Rhodobacter* can also grow heterotrophically on a variety of nutrients and can use either oxygen or nitrogen in the form of nitrate and nitrous oxide as terminal electron acceptor. Under these conditions, the ubiquinol that is formed by the various dehydrogenases can be oxidized by the *bc*₁ complex and electrons transferred via the *c* cytochromes to oxygen or nitrous oxide, or electrons from the quinol can bypass the *c*-cytochrome pool and be transferred directly to nitrate, nitrous oxide, or oxygen.

has the same electron transfer and proton translocation functionality as the mitochondrial enzymes. Possible functions for these nonredox subunits include docking sites for ternary complex formation with the dehydrogenase and oxidase complexes, regulation of half-of-the-sites activity of the dimeric enzyme, structural stability in the relatively long-lived eukaryotes, and protection against oxygen radicals.

Spectroscopic and Thermodynamic Properties of the *bc*₁ Complex

The *bc*₁ complex is visibly red due to the cytochromes. Optical spectra of the yeast enzyme in the visible region of the spectrum are shown in Figure 2. When the enzyme is reduced by dithionite, a difference spectrum of the dithionite-reduced

Figure 2 Optical spectra of the yeast cytochrome bc_1 complex. Difference spectra of (a) the dithionite-reduced vs. ferricyanide-oxidized enzyme and (b) the ascorbate-reduced versus ferrocyanide-oxidized enzyme. (c) Calculated difference spectrum, obtained by subtracting the spectrum of the ascorbate-reduced enzyme from the spectrum of the dithionite-reduced enzyme.

versus ferricyanide-oxidized enzyme exhibits an absorption maximum at 562 nm due to ferro-cytochrome b and a shoulder at ~ 553 nm due to ferro-cytochrome c_1 . When the enzyme is reduced with ascorbic acid, the reduced versus ferricyanide-oxidized difference spectrum consists of only cytochrome c_1 , with a maximum at 553 nm (Figure 2(b)). The extinction coefficient of reduced versus oxidized cytochrome c_1 at 553 nm versus 539 nm is $17.5 \text{ mM}^{-1} \text{ cm}^{-1}$, which was obtained from the purified protein. By subtracting the spectrum of c_1 from that of $b + c_1$, it is possible to derive a calculated difference spectrum of the cytochrome b as shown in Figure 2(c). The extinction coefficient of reduced versus oxidized cytochrome b at 562 versus 575 nm is $25.6 \text{ mM}^{-1} \text{ cm}^{-1}$, which was determined by measuring the fluorescence quenching upon stoichiometric binding of antimycin to the bovine enzyme. This value is an average of the two b hemes. The individual extinction coefficients of the b_H and b_L hemes have not been determined for most bc_1 complexes, but the contribution from the b_H heme at 562 is significantly greater than that from the b_L heme, which has a split absorption maximum with peaks at 564–566 and ~ 558 nm.

The Rieske iron–sulfur protein is a pale yellow-gold color when isolated from the bc_1 complex in the oxidized form but bleached to colorless when reduced and thus makes no contribution to the optical spectrum of the reduced enzyme. The redox status of the $2\text{Fe}-2\text{S}$ cluster is monitored by electron paramagnetic resonance (EPR) spectroscopy as the reduced cluster is paramagnetic. The Rieske cluster exhibits a unique EPR spectrum with peaks at approximately $g_x = 1.76$, $g_y = 1.90$, and $g_z = 2.03$, resulting in $g_{av} = 1.90\text{--}1.91$, which is atypical of binuclear iron–sulfur clusters. The unusual EPR spectrum of the Rieske protein is due to bis-histidine coordination of one of the two iron atoms, which was first suggested by spectroscopic studies and confirmed by crystal structures of the enzyme.

The midpoint potentials of the redox centers in the bc_1 complex determine the thermodynamic parameters and in some cases control electron transfer reactions within the enzyme. In *S. cerevisiae* the midpoint potentials at pH 7 are as follows: cytochrome c_1 , +240 mV; Rieske iron–sulfur cluster, +280 mV; cytochrome b_H , +120 mV; and cytochrome b_L , –30 mV. Although there are species differences in these midpoint potentials, it is generally true that the midpoint potential of the Rieske center is $\sim 20\text{--}40$ mV more positive than that of c_1 , and that of the b_L heme is 60–120 mV lower

Figure 3 Thermodynamic profile of the *Saccharomyces cerevisiae* cytochrome bc_1 complex. The figure illustrates the thermodynamic relationship between the redox components of the cytochrome bc_1 complex. Arrows indicate electron transfer reactions in the enzyme. The redox groups are arranged vertically according to their oxidation–reduction potentials, with the center of the boxes positioned vertically at the midpoint potentials of the redox groups. The open boxes depict the approximate range of potentials spanned by the redox components as their oxidation–reduction status varies in response to changes in rates of electron transfer. The midpoint potentials of the redox components are cytochrome b_L , –30 mV, cytochrome b_H , +120 mV, cytochrome c_1 , +240 mV, and Rieske iron–sulfur protein, +280 mV.

than that of the b_H heme. The midpoint potentials of the b hemes are influenced by the detergents used to purify the enzyme, and may be similarly influenced by bound phospholipids. The midpoint potential at pH 7 of ubiquinone is +90 mV in the membrane, but this value may be altered by preferential binding of either quinone or quinol to reaction

Figure 4 Crystal structure of the cytochrome *bc*₁ complex. The structure in (a) is of the yeast *bc*₁ complex with stigmatellin bound, resolved to 2.3 Å by Hunte and co-workers, and shows all of the subunits of the enzyme dimer, except subunit 10, which is lost during purification. The structure is oriented so that the mitochondrial matrix would be at the bottom and the intermembrane space at the top of the figure. Cytochrome *b* is colored cyan, cytochrome *c*₁ red, and the Rieske protein blue. The supernumerary subunits are colored gray. The heme groups (heme *b*_L and heme *b*_H) are shown as stick structures, colored green. Stigmatellin (Stg) bound at center P in only one monomer is shown as a stick structure, with carbon atoms colored yellow and oxygen atoms red. Ubiquinone (Ubi) bound at center N in only one monomer is also shown as a stick structure, with carbon atoms colored yellow and oxygen atoms red. The iron-sulfur cluster (FeS) is shown with its van der Waals radius, with iron atoms colored purple and sulfur atoms colored yellow. The structure in (b) is of a functional monomer, consisting of cytochrome *b* and cytochrome *c*₁ from one monomer and the Rieske protein from the other. Ubiquinol (QH₂) containing two isoprenyl groups is hydrogen-bonded between His181 of the Rieske protein and Glu272 of cytochrome *b* to form a putative electron-donor complex. An energy-minimized structure of the docked quinol was obtained by replacing stigmatellin in the crystal structure, followed by molecular dynamics and energy minimization calculations. The protein subunits, heme groups, and ubiquinol are colored as in (a).

sites in the enzyme. These midpoint potentials result in a thermodynamic profile of the *bc*₁ complex as shown in Figure 3.

Three-Dimensional Structure of the *bc*₁ Complex

Cytochrome *bc*₁ complexes from bovine, chicken, and yeast mitochondria have been crystallized and their structures solved to atomic resolution. The yeast enzyme, shown in Figure 4, is the highest-resolution structure available at this time. The mitochondrial *bc*₁ complex is a symmetrical, oligomeric dimer, in which the three redox subunits are surrounded by a periphery of nonredox, supernumerary subunits. The dimeric structure of the enzyme was suspected from hydrodynamic measurements and confirmed by the first crystal structure of the bovine enzyme. Although the bacterial enzyme has not yet been crystallized, it will presumably turn out to be a dimeric structure too, but lacking the large number of supernumerary subunits.

One unusual aspect of the dimeric structure is that the iron-sulfur protein spans the dimer. The Rieske protein is anchored in one monomer by a single transmembrane helix, as shown in Figure 4(a), while the peripheral domain that contains the 2Fe-2S cluster is located in the other monomer, where it forms part of the ubiquinol oxidation site. Crystal structures of the chicken *bc*₁ complex in the absence and presence of stigmatellin, an inhibitory ligand, also provided

striking evidence that the peripheral domain of the Rieske protein moves back and forth between positions proximal to cytochrome *b* and cytochrome *c*₁. This suggested that movement of the Rieske protein facilitates electron transfer, which was confirmed by site-directed mutagenesis studies that demonstrated that such movement of the Rieske protein was essential for enzyme activity.

Functionally, the enzyme consists of the cytochrome *b* and *c*₁ subunits from one monomer and the Rieske protein from the other, as shown in Figure 4(b). The crystal structures established the location of the sites of ubiquinol oxidation and ubiquinone reduction at topographically separated sites within the enzyme. The structures also confirmed the transmembrane disposition of the *b* hemes, which form a conduit through which electrons are cycled across the membrane in which the enzyme resides. These structural details provided the final confirmatory evidence of the protonmotive Q cycle mechanism of the enzyme.

Mechanism of the Enzyme

The Protonmotive Q Cycle

The *bc*₁ complex oxidizes ubiquinol and transfers two electrons to two molecules of cytochrome *c*. During this electron transfer reaction, two protons are taken up from the mitochondrial

Figure 5 Mechanism of electron transfer through the cytochrome *bc*₁ complex. The scheme shows the pathway of electron transfer from ubiquinol to cytochrome *c* through the redox centers of the cytochrome *bc*₁ complex. The circled numbers designate electron transfer reactions. Dashed arrows designate movement of ubiquinol (QH₂) or ubiquinone (Q) between center P on the positive side of the membrane and center N on the negative side of membrane, and movement of the iron-sulfur protein between cytochrome *b* and cytochrome *c*₁. Solid black bars indicate sites of inhibition by antimycin, funiculosin, illicicoline, myxothiazol, UHDBT, and stigmatellin. In reaction 1, ubiquinol oxidation delivers two electrons divergently to the Rieske iron-sulfur cluster and the *b*_L heme, two protons are released, and the resulting ubiquinone leaves center P. In reaction 2, the reduced Rieske cluster oscillates to within electron transfer distance of cytochrome *c*₁, resulting in electron transfer from the iron-sulfur cluster to the *c*₁ heme. In reaction 3, an electron is transferred from the *b*_L to *b*_H heme, which in turn reduces ubiquinone to ubiquinol (reaction 4). Following oxidation of a second ubiquinol at center P and reduction of the *b* cytochromes the *b*_H heme reduces ubiquinol to ubiquinol (reaction 5), accompanied by uptake of two protons at center N.

matrix or bacterial cytoplasm and four protons are deposited on the other side of the membrane. The mechanism by which the *bc*₁ complex links the electron transfer and proton translocation reactions is the protonmotive Q cycle, as shown in Figure 5. In the Q cycle mechanism proton translocation is the net result of topographically segregated reduction of quinone and reoxidation of quinol on opposite sides of the membrane, with protons being carried across the membrane as hydroxyl hydrogen atoms on the quinol. The sites where quinone is reduced and quinol is oxidized are referred to as center N and center P, respectively, as they are located toward the electronegative and electropositive sides of the membrane. Protons are taken up at center N, carried across the membrane by the quinol, and released at center P.

In the first step of the Q cycle, ubiquinol is oxidized at center P in a reaction that divergently transfers the two electrons from ubiquinol to the Rieske iron-sulfur cluster and the cytochrome *b*_L heme (reactions 1a–1c in Figure 5). In reaction 2, the reduced Rieske cluster oscillates to within electron transfer distance of cytochrome *c*₁ and an electron is transferred from the iron-sulfur cluster to the *c*₁ heme. Two protons are released from center P coincident with ubiquinol oxidation. In reaction 3, an electron is transferred from the *b*_L to *b*_H heme, which in turn reduces ubiquinone to ubiquinol (reaction 4). Following oxidation of a second ubiquinol at center P and reduction of the *b* cytochromes the *b*_H heme reduces ubiquinol to ubiquinol (reaction 5), accompanied by uptake of two protons at center N.

There is evidence that the mitochondrial *bc*₁ complex functions by an alternating-site mechanism, in which binding of ubiquinol in one monomer exerts negative cooperativity on binding of ubiquinol in the other monomer. If the enzyme can be switched from a form in which ubiquinol oxidation alternates between the two monomers to a form where both monomers are simultaneously active, it would provide a mechanism to regulate the activity of the enzyme, perhaps in response to cellular energy needs. Whether such a regulatory mechanism exists and, if so, how it operates, is not known.

Proton Conduction Pathways

In the Q cycle mechanism, protons are carried across the membrane as hydrogen atoms on the hydroxyl groups of ubiquinol. However, the sites where ubiquinol is oxidized at center P and ubiquinol is reduced at center N are not freely accessible to the bulk aqueous phase at the membrane surface. Consequently, the linkage of proton chemistry to electron transfer requires mechanisms for moving protons to and from the aqueous phase and the hydrophobic sites of quinol and quinone redox reactions.

The crystal structures of the *bc*₁ complex with bound stigmatellin (Figure 4(a)) show that the inhibitor is hydrogen-bonded between His181 (in the yeast numbering system) of the Rieske protein, which is a ligand to the iron-sulfur cluster, and Glu272 of cytochrome *b*. As stigmatellin presumably

mimics an intermediate in ubiquinol oxidation, this suggests that ubiquinol forms an electron-donor complex involving hydrogen bonds between the quinol hydroxyl groups and these two amino acids, as shown in [Figure 4\(b\)](#).

When ubiquinol reduces the Rieske protein, an electron is transferred to the iron–sulfur cluster, while a proton from the quinol hydroxyl group protonates the imidazole nitrogen on His181 of the Rieske protein. The Rieske protein acts as a hydrogen carrier and releases the proton to the aqueous phase when it moves proximal to cytochrome *c*₁ and is oxidized. The second proton from ubiquinol is transferred to Glu272 and then to a propionate of the cytochrome *b* heme as an electron is transferred to the *b*_L heme. From the crystal structure of the yeast enzyme it appears that this proton can then access the aqueous surface from the *b*_L heme via a conserved arginine (Arg79). In this manner, two protons are released from center P with minimal charge separation as the two electrons are divergently transferred from the quinol to the high-potential and low-potential electron acceptors ([Figure 3](#)).

The crystal structure of the yeast enzyme has also revealed pathways for conduction of two protons into center N. One of these pathways, the (CL)/K pathway, involves a conserved lysine and a bound cardiolipin, which may function as a buffer to concentrate protons at the entrance to the pathway. The second proposed proton conduction pathway at center N is referred to as the E/R pathway and involves a conserved glutamate and a conserved arginine. The high resolution of the yeast crystal structure also reveals that one or two bound water molecules may serve as direct proton donors during quinone reduction. Notably, whereas ubiquinol oxidation at center P proceeds with minimal charge separation, ubiquinone reduction at center N begins with substantial charge separation as electrons and protons enter the reaction site from opposite directions, and the redox reaction is accompanied by charge compensation, which enhances the reaction rate.

Inhibitors

There are numerous inhibitors that act on the cytochrome *bc*₁ complex and that bind specifically to either the ubiquinol oxidation site at center P or the ubiquinone reduction site at center N. These have proved to be especially useful in establishing the mechanism of the enzyme and for selectively blocking electron transfer reactions at either of the two reaction sites in the enzyme to facilitate kinetic analysis. In addition, some of the inhibitors have antifungal and antiparasitic activity.

Antimycin, funiculosin, and ilicicolin H are produced by microorganisms as defensive toxins and inhibit the *bc*₁ complex by binding to center N with near stoichiometric affinity. Under conditions of catalytic turnover, they block reduction of ubiquinone by cytochrome *b* by binding to the ubiquinone

reduction pocket at a site proximal to the *b*_H heme, causing electrons to accumulate in the *b* hemes. Under presteady-state conditions where the enzyme is reduced by ubiquinol, they block reduction of the *b*_H heme by quinol.

Stigmatellin, also produced by a microorganism, inhibits the *bc*₁ complex by binding to the ubiquinol oxidation pocket, simultaneously forming hydrogen bonds to the imidazole nitrogen of His181 on the Rieske protein and a carboxyl oxygen of Glu272 on cytochrome *b*. In this manner, the inhibitor locks the Rieske protein in a conformation proximal to cytochrome *b*. Stigmatellin raises the midpoint potential and shifts the EPR spectrum of the iron–sulfur cluster, indicative of its interaction with the Rieske protein.

Hydroxyquinones, such as UHDBT, a benzoxothiazole (3-undecyl-2-hydroxy-1,4-benzoxothiazole) and atovaquone, a hydroxynaphthoquinone (2-[*trans*-4-(4'-chlorophenyl) cyclohexyl]-3-hydroxy-1,4 hydroxy-naphthoquinone), also bind to the ubiquinol oxidation pocket and form a hydrogen bond to His181 of the Rieske protein. Like stigmatellin, these ligands raise the midpoint potential and change the EPR spectrum of the iron–sulfur cluster. However, the hydroxyquinone inhibitors do not hydrogen-bond to Glu272 of cytochrome *b*; instead, the crystal structure of the yeast *bc*₁ complex with an analog of UHDBT bound shows Glu272 rotated toward the heme propionate, which suggested the proton conduction pathway described above.

Methoxyacrylates, such as myxothiazol, also bind to the ubiquinol oxidation pocket but do not interact directly with the Rieske protein. These inhibitors bind proximal to the *b*_L heme and affect its spectral and thermodynamic properties.

Glossary

Apoptosis A means for the multicellular organism to eliminate cells that are no longer needed or are damaged, also called 'programmed cell death'.

Cytochromes Literally cell pigments, heme proteins chiefly involved in cell respiration and energy supply.

Heme An iron porphyrin complex that is attached (as a prosthetic group) to protein moieties in the red

blood pigment hemoglobin, in the cytochromes and in many other heme proteins.

Mitochondria Intracellular organelles, the main site of oxidative metabolism that supplies the cell with utilizable energy in the form of adenosine triphosphate. In the course of cellular respiration, elementary oxygen is taken up by mitochondria and reduced to water. The electrons required for reduction are transmitted to oxygen via the respiratory chain, one of the electron transporters being cytochrome *c*.

Cytochrome *c* is a heme protein that is present in and can easily be isolated from mitochondria of all eukaryotic organisms. The amino acid sequence of the protein moiety was among the first sequences that could be elucidated. This was the starting point for comparative studies about sequence variations found in cytochrome *c* from a wide range of species. A phylogenetic tree constructed on the basis of this information was found to be biologically significant and became exemplary for subsequent studies on molecular evolution. The function of cytochrome *c* in the respiratory chain as an electron carrier is well established. More recently, an additional role of cytochrome *c* was discovered: its release from mitochondria into the cytosol triggers apoptosis – the programmed cell death.

Introduction

Cytochromes are proteins that contain heme as their prosthetic group and whose principal biological function, in the cells of animals, plants, and microorganisms, is electron transport. The foundations of the knowledge of heme proteins and their roles as electron carriers in cell respiration were laid by David Keilin (1887–1963), ~80 years ago. In the cytochromes, the iron which is coordinately linked with four nitrogen atoms within the prosthetic group and with two additional ligands provided by the protein moiety, can alternate between a reduced Fe^{2+} and an oxidized Fe^{3+} state. Different classes of cytochromes (*a* type, *b* type, and *c* type) differ in the nature of their heme prosthetic groups. They can be observed and differentiated spectroscopically, on the basis of characteristic absorption bands. The absorption peaks of reduced cytochrome *c* and other *c*-type cytochromes (such as *c*₁) are at ~550, 520, 416, and 270 nm. The *b*-type and *a*-type cytochromes absorb visible light at higher wavelengths. In eukaryotic cells, cytochromes of types *a*, *b*, and *c* are found predominantly within mitochondria. In the mitochondrial respiratory chain, cytochrome *c* accepts electrons from complex III, which contains cytochromes *b* and *c*₁ (*bc*₁), and transmits them to complex IV (cytochrome oxidase), which has two heme prosthetic groups (*aa*₃). These respiratory complexes, with their respective cytochromes, are firmly integrated in the inner membrane of the

mitochondrion. Cytochrome *c*, by contrast, is only loosely bound in the space between the inner and outer mitochondrial membranes and shuttles between *bc*₁ and *aa*₃. As shown by Keilin and others, cytochrome *c* can be easily removed experimentally from and reincorporated into isolated mitochondria, their respiratory capacity thereby being impaired and restored, respectively. It has recently been discovered that the release of cytochrome *c* from mitochondria into the cytoplasm is an important step in programmed cell death. This participation in apoptosis of eukaryotic cells is now considered to be another significant function of cytochrome *c*.

Cytochrome *c* and *c*-type cytochromes occur in all eukaryotic organisms. The comparative analysis of the protein structures of cytochromes isolated from a multitude of different species of organisms has made it possible to establish evolutionary relationships between them. The phylogenetic tree based on the slow changes of the structure of cytochrome *c* in the course of evolution is most impressive and biologically relevant.

The *c*-type cytochromes are also present in prokaryotes, where they may function in a respiratory chain or in photosynthesis; examples are cytochrome *c*₂ from *Rhodospirillum rubrum* (purple bacteria) and cytochrome *c*₅₅₁ from *Pseudomonas aeruginosa* (Gram-negative bacteria). These are distantly related to mitochondrial cytochromes *c*; however, a more detailed discussion of these diverse hemoproteins is outside the scope of this article.

Attachment of the Heme Prosthetic Group to Cytochrome *c* Apoprotein

The prosthetic group of *c*-type cytochromes, such as cytochrome *c* and *c*₁ in mitochondria and cytochrome *f* in chloroplasts, unlike that of *a*- and of *b*-type cytochromes, is covalently linked to the polypeptide moiety. The thiol groups of two cysteinyl residues in a Cys–X–Y–Cys–His peptide motif are attached to two vinyl groups of heme through thioether bonds. This linkage is resistant to heat and hydrolysis, but can be broken with the help of silver or mercury salts. Thus, the polypeptide moiety of cytochrome *c*, or of heme peptides derived from it by proteolytic cleavage, could be obtained. In

eukaryotic cells, the apoprotein of cytochrome *c* is encoded by a nuclear gene, translated on cytoplasmic ribosomes, and translocated into the intermembrane space of mitochondria, where an enzyme, cytochrome *c* heme lyase, combines it with heme. An *in vitro* synthesis of a microbial *c*-type cytochrome from its apoprotein and reduced heme has recently been achieved.

Amino Acid Sequence Studies

Cytochrome *c* is a small, water-soluble protein that can easily be isolated and purified from cells and tissues of many different eukaryotic organisms. In proteolytic digests of cytochrome *c*, one fragment containing the covalently linked heme group can be separated from all the other ones. Studies on the amino acid sequence of these heme peptides isolated from cytochromes *c* of diverse origin thus became feasible. It turned out that certain sequence elements, as the one mentioned in the Introduction, were highly conserved from yeast to mammalian cytochromes *c*.

Expanding on this early work, cytochrome *c* from horse heart was one of the first proteins whose complete amino acid sequence could be determined. It consists of a single polypeptide chain of only 104 residues that could be analyzed even with, by modern standards, rather primitive tools available around 1960. The protein contains many (up to 19) lysine residues, whose positive charges can form ionic bonds with constituents of the inner mitochondrial membrane.

With the horse sequence as a reference, cytochrome *c* isolated from diverse species was subsequently analyzed in quick succession. These included other mammals (human, rhesus monkey, pig, dog, rabbit, whale, and kangaroo), birds (chicken, pigeon, king penguin, and turtle), reptiles (rattlesnake and alligator), amphibia (bullfrog), fish (tuna, carp, and dogfish), and the chordate pacific lamprey. Further, with unabated pace, additional sequences were determined for cytochromes *c* from flies, moths, yeasts, *Neurospora*, and a large variety of plants. By now, we know the sequence of this protein from more than 100 eukaryotic species. As a result of these efforts, cytochrome *c* became the first and still is a standard example for studies on the molecular evolution of proteins. Nuclear genes encoding cytochrome *c* have been analyzed from various species. The mammalian gene contains a small intron in the coding sequence and a larger one upstream of the initiation codon.

The recent progress in the sequencing of whole eukaryotic genomes has also yielded information about the number of cytochrome *c* genes in various species. For example, in the human genome, a single gene for cytochrome *c* is present on chromosome 7, along with 49 pseudogenes located on many different chromosomes. These are mostly processed pseudogenes, which were formed by retro-transcription of a messenger RNA. In rodents, two cytochrome *c* genes are expressed, one of them exclusively in the testis. This latter gene is still present as a pseudogene in the human genome.

Evolutionary Aspects

Cytochrome *c* is a highly conserved protein, which retained many structural characteristics over the eons of evolution of

animals and plants. This makes it an ideal tool for amino acid sequence comparisons over a wide range of species (Figure 1). From the sequence differences, a molecular pedigree can be constructed based on the original assumption, now corroborated by many examples, that the longer ago the common ancestor of two species existed, the more amino acid changes will have accumulated since. As it turned out, the phylogenetic trees constructed on the basis of the sequence of a single protein were surprisingly similar to those derived from comparative anatomy, fossils, etc. Moreover, as cytochrome *c* could be extracted from species for which no reliable data were available from other sources, these could now also be included in this analysis.

In this comparison of cytochromes *c* from diverse eukaryotic species, it was found that more than a quarter of the amino acids have been conserved during more than a billion years of evolution. Among these immutable residues are the two cysteines to which the heme is bound via thioether linkages. The central iron of the planar heme is bound not only to four nitrogen atoms of the porphyrin but also to the side chains of two invariant amino acids of the protein, one being a histidine adjacent to the second cysteine (residue #18 in the vertebrate sequences), the other the sulfur atom of methionine 80, present on opposite sides. Moreover, certain amino acids with hydrophobic side chains, some of which line the crevice where the heme is buried, are also conserved. Surprisingly, it was found that several glycine residues in the sequence were also invariant. Glycine is the smallest amino acid containing only a hydrogen atom where the 19 others have more or less

Figure 1 Phylogenetic tree constructed from the amino acid sequences of cytochrome *c* using the ClustalW program. The length of the branches corresponds to evolutionary distances (0.1 = 10% amino acid substitutions).

bulky side chains. From the three-dimensional structure, this first puzzling observation could be explained. At these sites, there is simply no space in this tightly folded protein and every other amino acid would presumably prevent proper folding of the polypeptide chain and thus be deleterious. In addition, some charged amino acids, mostly lysines, have been conserved. These may be essential for the ionic interaction with two of its reaction partners, as well as with acidic phospholipids present in the inner mitochondrial membrane.

Three-Dimensional Structure

Using X-ray crystallographic analysis, the three-dimensional structure of tuna cytochrome *c* in its oxidized and reduced forms could be determined. As shown by these studies, the polypeptide chain is tightly wrapped around the heme, which sits in a deep pocket, exposed only on one edge to the solvent. In accordance with the oil-droplet model of folded proteins, the hydrophobic amino acids are mostly buried inside the protein, some of them surrounding the heme. In the respiratory chain located in the inner membrane of mitochondria, cytochrome *c* shuttles between a reduced ferro- (Fe^{2+}) and ferri- (Fe^{3+}) form. In this redox cycle, the protein changes its conformation, with the reduced form having a more compact structure.

Interactions of Cytochrome *c* in the Respiratory Chain

Cytochrome *c* is loosely bound to the outer surface of the inner mitochondrial membrane. In the respiratory chain, an electron is transferred to cytochrome *c* from cytochrome *bc*₁. These cytochromes are part of a large, membrane-bound complex, also termed complex III composed of 11 proteins. Subsequently, the electron is delivered to the cytochrome *aa*₃ of the complex IV, the cytochrome oxidase, which contains 13 proteins. Some of the molecular details of this electron transport have recently also been clarified. In the crystal structure of the yeast cytochrome *bc*₁ complex with its bound substrate cytochrome *c*, the heme groups of cytochrome *c*₁ and *c* are in close proximity (see Figure 2). This suggests that the redox process takes place by direct heme-to-heme electron transfer. The same may also be true for the oxidation of cytochrome *c* by cytochrome *aa*₃.

In both redox reactions, a proton is pumped across the inner membrane. The proton gradient thus formed drives the adenosine triphosphate (ATP) synthetase motor, which results in the synthesis of ATP.

Cytochrome *c* and Apoptosis

Cells that are damaged or are no longer needed may undergo a form of cell death that is controlled and executed by intracellular programs. One major apoptotic program involves the release of cytochrome *c* from the intermembrane space of mitochondria into the cytosol, together with some other mitochondrial proteins. Once in the cytoplasm, cytochrome *c* combines with an apoptosis activating factor-1 (Apaf-1) and thus triggers the assembly of a multimeric protein complex, the so-called apoptosome. An inactive proform of a proteolytic enzyme, procaspase-9, is then recruited to the apoptosome and activated. Active caspase-9, in turn, activates other

Figure 2 Part of the yeast cytochrome *bc*₁ complex and the bound substrate cytochrome *c* (Protein Data Bank, accession number 1KY0). Cytochrome *c*₁, yellow; cytochrome *c*, magenta; hemes, red.

caspases, whose proteolytic actions finally lead to cell death. The crucial role of cytochrome *c* in this process is shown by the fact that microinjection of cytochrome *c* into the cytoplasm suffices to induce apoptosis in several cell lines. In the interaction with Apaf-1, as in the interaction with cytochrome *c*₁, the exposed heme edge of cytochrome *c* is involved.

When cytochrome *c* molecules are released from the mitochondrion, they have to pass through pores in the outer membrane of the organelle. A group of related proteins, the Bcl-2 family, regulates apoptosis by controlling the permeability of this membrane. Bcl-2 itself and other antiapoptotic proteins are located in the outer mitochondrial membrane and inhibit cytochrome *c* release. Conversely, release of cytochrome *c* is triggered by proapoptotic members of the Bcl-2 family, which are induced by a number of stimuli to translocate to the mitochondria. Since one of the functions of apoptosis is to help the multicellular organism to eliminate cancer cells, the pro- and antiapoptotic Bcl-2 family members are considered to be oncogenic and antioncogenic proteins, respectively. They control whether cytochrome *c*, besides being a vital mediator of electron transfer in respiration, also gets involved in cell death.

Glossary

Aerobe Organism that uses oxygen (O₂) as the terminal electron acceptor in respiration.

Cytochrome A heme protein serving as an electron carrier.

Proton electrochemical gradient Sum of the contributions of the proton concentration difference (pH) and voltage across a membrane (in units of energy, e.g., kJ mol⁻¹ or eV).

Proton pump Integral membrane protein that translocates protons across the membrane without the use of mobile

proton carriers (which would bodily carry protons across the membrane, e.g., a quinone).

Proton-transfer pathway Typically, an arrangement of protein-bound water molecules and hydrophilic or protonatable amino acid residues used for the transfer of a proton from a donor to an acceptor (where one of these may be the bulk solution).

Redox-active cofactor or redox site Group within a protein (e.g., a metal ion) that can accept and give electrons in its oxidized and reduced states, respectively.

Bacterial cytochrome *c* oxidases are integral membrane proteins that catalyze the four-electron reduction of dioxygen (O₂) to water and oxidation of different types of water-soluble or membrane-anchored cytochromes *c* (cyt.*c*). The oxygen-reducing site of the enzymes consists of a heme–copper center, which is buried within the protein. Hence, cytochrome *c* oxidases belong to the superfamily of heme–copper oxidases, a class of enzymes that also includes the quinol oxidases, which use different types of lipid-soluble quinols (QH₂) instead of cytochrome *c* as their electron donor. The heme–copper oxidases are also often termed ‘respiratory oxidases’ or ‘terminal oxidases’, terms that refer to the enzymes being the last components of the respiratory chains of aerobic organisms. However, not all terminal oxidases belong to the heme–copper oxidase superfamily. One example is the group of so-called alternative oxidases (e.g., in plants), which do not contain any heme groups.

Chemical Process

In the cytochrome *c* oxidases the protons used for O₂ reduction to water (substrate protons) are taken up from the inner (cytosol) side of the membrane, while cytochrome *c* reacts on the opposite, outer (periplasm) side of the membrane. In the quinol oxidases, the quinol binds from the core of the membrane and, upon oxidation, the protons are released to the periplasm. Thus, the reaction catalyzed by the heme–copper oxidases has a direction not only in time (cf. any chemical reaction), but also in space, which is referred to as ‘vectorial chemistry’. The charge distribution across the membrane is such that there are more positive charges on the outer side than on the inner side. Hence, the outer and inner sides are referred to as the positive (*P*) and negative (*N*) sides, respectively:

where the subscripts *N* and *P* refer to the negative and positive sides, respectively. In both cases outlined above, a net of four positive charges are generated on the *P*-side, while four positive charges are consumed on the *N*-side. Consequently, the chemical reactions catalyzed by heme–copper oxidases are arranged topographically in such a way that they result in a charge separation corresponding to the net transfer of one positive charge from the *N*-side to the *P*-side of the membrane per electron transferred to O₂. In addition, for most heme–copper oxidases characterized to date, part of the free energy released in the catalytic reaction is also used to pump (translocate) protons from the *N*-side to the *P*-side of the membrane, with an average stoichiometry of one proton per electron (see Figure 1 and more detailed discussion below). Hence, on average, two charges are transferred across the inner membrane per electron transferred to oxygen. As suggested by Peter Mitchell and formulated in the chemiosmotic theory, this transmembrane proton and voltage gradient generated in part by the heme–copper oxidases is used, for example, for synthesis of adenosine triphosphate (ATP) by the ATP synthase.

Structures

The bacterial heme–copper oxidases consist of several (in many cases four) subunits, located in the (inner) cell membrane of the bacterium. The minimal functional unit of the heme–copper oxidases is the subunit (SU) I–II complex (see also below). The heme–copper oxidase family is defined by the presence in SU I of six conserved histidine residues that coordinate three redox-active metal sites: (1) a six-coordinated heme group which has two axial His ligands and in which the iron ion is in a low-spin state; (2) a five-coordinated heme group with one axial His ligand and in which the iron ion generally is found in the high-spin state; and (3) a copper ion (Cu_B) which is bound by three His ligands. The SU I scaffold, which holds the redox centers, comprises at least 12 transmembrane helices, which span the membrane. The five-coordinated heme is usually denoted with a subscript 3, for example, heme *a*₃. In the examples and discussion below,

Figure 1 (a) The overall structure of the *Rhodobacter sphaeroides* cytochrome *aa*₃ (cytochrome *c* oxidase). Subunits I, II, III, and IV are shown in different colors as indicated. The heme groups are shown in yellow, the copper ions in blue, and a redox inactive Mg^{2+} ion in green. Three redox active sites, heme *a*, and the catalytic site consisting of heme *a*₃ and Cu_B are found in SU I. The Cu_A center is found in SU II. A likely location of the cytochrome *c* binding site is indicated. Water molecules resolved in the structure are shown as red spheres. (b) Only the cofactors are shown together with the water molecules resolved in the structure. Substrate and pumped protons (thick arrows) are taken up from the inner, cytosol side (N-side) and the pumped protons (dashed arrow) are released on the outer, periplasm side (P-side), as shown. e^- is the electron from cyto *c* (thin arrows). (c) Top view of the enzyme. (d) The redox-active cofactors (and the Mg^{2+} ion) and proton-transfer pathways of cytochrome *c* oxidase. The overall reaction catalyzed by cytochrome *c* oxidase is described by the reaction formula, where the subscripts *P* and *N* refer to the two sides of the membrane. Subunits I–III of the *R. sphaeroides*, *Paracoccus denitrificans*, and the mitochondrial enzymes are highly homologous and their overall structures are very similar.

we call the two hemes of the enzyme hemes *a* and *a*₃, respectively.

Unlike the six-coordinated heme, heme *a*₃ binds ligands such as O_2 , CO, and CN^- . Heme *a*₃ and Cu_B are collectively called the binuclear center, which is the catalytic site at which O_2 is reduced to water. The heme groups may be of different types, such as heme *a*, *b*, or *o*, where the two hemes in SU I may

be of the same or of different types. Heme–copper oxidases are also often given a name that indicates the types of hemes present, for example, cytochrome *aa*₃. Many bacteria have several types of oxidases, which are expressed to various degrees depending on the environmental conditions (e.g., the O_2 concentration). The X-ray structures of heme–copper oxidases that have been determined to date are summarized in Table 1.

A common feature of most (but not all) cytochrome *c* oxidases is a copper center (Cu_A) bound in SU II, which is the primary electron acceptor from cytochrome *c*. Hence, the binding site for the water-soluble cytochrome *c* is located near Cu_A (see **Figure 1**). The Cu_A center is composed of two copper ions coordinated by two –SH groups of two Cys residues (among other ligands), which resembles the [2Fe–2S] centers of iron–sulfur proteins. The Cu_A center can accept and donate one electron switching between the formal charges [Cu¹⁺–Cu¹⁺] and [Cu^{1.5+}–Cu^{1.5+}] in the reduced and oxidized form, respectively. Many cytochrome *c* oxidases that do not have the Cu_A site instead have a cytochrome *c* subunit that protrudes into the inter-membrane space and acts as the primary electron acceptor. In the ubiquinol oxidase from *Escherichia coli*, the ubiquinol binding site was suggested from an analysis of the three-dimensional (3D) structure and from experiments using site-directed mutagenesis to be found in the membrane-spanning part of SU I at a cluster of polar residues exposed to the interior of the lipid bilayer.

Subunit III does not contain any redox-active cofactors. Even though the enzyme with SU III removed displays O₂-reduction activity and pumps protons (although with a stoichiometry of less than one proton per electron), this form of the enzyme becomes inactivated after a limited number of reaction cycles. Consequently, SU III is important for the stability of the protein.

Proton-Transfer Pathways

As seen in **Figure 1**, the O₂-reducing site is located in the membrane-spanning part of the enzyme. Therefore, proton-transfer pathways, leading from the protein surface on the *N*-side to the binuclear center, are needed. Such pathways are typically composed of polar and protonatable amino-acid residues as well as of water molecules forming a hydrogen-bonded chain. The detailed composition of these pathways varies in the bacterial heme–copper oxidases. Two pathways have been identified from an analysis of the 3D structures of heme–copper oxidases determined to date, from a comparison of the amino acid residue sequences of a large number of other heme–copper oxidases, and from the combined use of site-directed mutagenesis and functional studies. These pathways are found in SU I and are named the D- and K-pathways, after residues Asp(D)132 and Lys(K)-362, respectively. We use the *Rhodobacter sphaeroides* cytochrome *aa*₃ amino-acid residue numbering because the structure shown in **Figure 1** is from that enzyme. Both pathways start at the inner-side surface and lead to the catalytic site (**Figures 1** and **2**). A common feature of a large number of oxidases is a Glu residue in the D-pathway, E(I-286) in the *R. sphaeroides* cytochrome *aa*₃, located about 25 Å from D(I-132) and about 10 Å from the binuclear center. In heme–copper oxidases in which the Glu is not

Figure 2 The reaction cycle of cytochrome *c* oxidase. State **O** is the oxidized enzyme. The two-electron-reduced catalytic site (state **R**) binds O_2 (forming state **A**). In the first step of O_2 reduction, a ferryl state is formed (**P**), where one electron and one proton are transferred from a Tyr residue at the catalytic site. The transfer of the third electron to the catalytic site is accompanied by proton uptake from the bulk *N*-side solution and the formation of state **F**. In the next step, the fourth electron is transferred to the binuclear center associated with proton uptake from the bulk *N*-side solution.

conserved, other protonatable residues are found at about the same location in space.

Oxygen Binding and Reduction

Even though the reduction of O_2 to water is a highly exergonic reaction, the O_2 molecule is kinetically stabilized against reduction due to two factors. First, the one-electron reduction of O_2 to form the superoxide radical $O_2^{\bullet -}$ is associated with a positive free energy change, which imposes a thermodynamic barrier in the initial step of the reduction process. Second, in the ground electronic state, O_2 has two unpaired electrons (triplet state), which imposes spin restrictions on many of its reactions. The heme-copper oxidases overcome these problems by binding O_2 to the heme a_3 iron in the high-spin state and by providing a second electron donor, Cu_B , in the immediate vicinity. The rates at which bacterial oxidases catalyze the O_2 reduction are remarkably rapid with turnover numbers of up to several hundred O_2 molecules per second. The rapid uptake of O_2 may be facilitated by hydrophobic channels leading from the membrane core to the catalytic site, as suggested from analyses of the crystal structures of heme-copper oxidases.

The mechanism of the O_2 -reduction has been primarily investigated in detail in cytochromes aa_3 from *R. sphaeroides*, *Paracoccus denitrificans*, the closely related mitochondrial enzyme, as well as in cytochrome bo_3 from *E. coli*. The reaction sequence is most likely the same for all oxidases, but the mechanism described below has been identified primarily from studies of these enzymes.

Initially, the electrons are transferred one at a time to the binuclear center. When both heme a_3 and Cu_B are reduced

(i.e., $Fe_{a_3}^{2+}$ and Cu_B^+ , state **R** in Figure 2), O_2 binds to heme a_3 (the state is called **A**). After binding of O_2 the O–O bond is cleaved, which results in formation of a ferryl group ($Fe_{a_3}^{4+} = O$, see Figure 2), where one electron and a proton are donated by an internal group, presumably a highly conserved Tyr at the catalytic site, which would form a radical. Even though the binuclear center is in a two-electron reduced state, formally four electrons are donated to O_2 in this reaction because two electrons are donated by Fe_{a_3} ($Fe_{a_3}^{2+} \rightarrow Fe_{a_3}^{4+}$), one by Cu_B ($Cu_B^+ \rightarrow Cu_B^{2+}$) and one by the Tyr. For historical reasons, this state is called ‘peroxy’ and denoted **P**.

The transfer of the third electron to the binuclear center is associated with proton uptake from the inside bulk solution. The intermediate that is formed is called ‘ferryl’ and is denoted **F** (Figure 2). It is assumed to have the same chemical structure as **P**, except for the additional electron and proton at the binuclear center, which are presumably transferred to the Tyr radical. The transfer of the next, fourth electron to the binuclear center is also associated with proton uptake from the inside bulk solution and results in formation of the oxidized binuclear center, denoted **O**.

Proton Pumping

In 1977, Mårten Wikström showed that in addition to the charge separation associated with the O_2 reduction reaction, cytochrome *c* oxidase also releases protons to the *P*-side of the membrane. In other words, the enzyme is a proton pump, which translocates one proton from the *N*-side to the *P*-side of the membrane per electron transferred to O_2 . Consequently, since there is no proton carrier in the enzyme that can bodily

move protons across the membrane, there must be a specific mechanism by which the enzyme uses the free energy from reduction of O_2 to translocate protons across the membrane. This function must be reflected in specific structural elements of the molecular machine. The molecular mechanism by which heme–copper oxidases pump protons is not known. The general view is that during the process the enzyme must provide an alternating access of protons to the two sides of the membrane and have this alteration strictly coupled to specific transitions of the catalytic cycle. Such changes in the accessibility for protons to the two sides of the membrane are likely to be achieved by breakage and formation of hydrogen bonds in the proton-transfer pathways, for example, through local rearrangements of amino acid residue side chains. It has been shown that the $R \rightarrow P$ transition is not associated with proton pumping, while the $P \rightarrow F$ and $F \rightarrow O$ transitions are associated with the translocation of one proton in each step. The definite assignment of other reaction steps in which proton translocation occurs and conditions under which this takes place is at present not definitely settled.

As indicated above, in the initial step of the reaction, the O_2 molecule is formally reduced by four electrons (to form state P, [Figure 2](#)). An advantage of such a four-electron reduction of O_2 in a single step is that it prevents accumulation of potentially harmful, partly reduced O_2 intermediates. However, since the formation of P is not associated with proton translocation, this mechanism requires that the free energy available from the O_2 -reduction reaction is conserved within the enzyme, for example, by the formation of high- pK_a internal proton acceptors; and the free energy can be used for proton translocation in the following steps of the reaction.

Some Experimental Techniques Used to Study Heme–Copper Oxidases

Present knowledge about the O_2 -reduction mechanism is derived from the use of a large number of experimental techniques. One of these is the flow-flash technique, pioneered by Quentin Gibson and Colin Greenwood. The enzyme reduced with 2–4 reduction equivalents and with CO bound to heme a_3 is mixed with an O_2 solution after which the CO ligand is flashed off by means of pulsed illumination, which initiates the reaction of the enzyme with O_2 . The application of this technique has made it possible to observe, with microsecond time resolution, the transitions between different states. The progress of the reaction is followed, for example, by observing absorbance changes of the redox sites, by measuring voltage

changes that originate from the movement of charges in enzyme reconstituted in lipid vesicles, or by using time-resolved resonance-Raman spectroscopy to obtain information about the structure of the oxygen intermediates. In addition, Fourier transform infrared difference spectroscopy is used to identify specific residues that undergo changes in their protonation state and/or hydrogen-bonding patterns, and electron paramagnetic resonance spectroscopy is used to explore the electronic configuration and the chemical environment of the redox centers. The use of the techniques discussed above, combined with the use of site-directed mutagenesis, has provided important insights into the catalytic mechanism.

Cytochrome P-450

R Bernhardt, Saarland University, Saarbrücken, Germany

© 2013 Elsevier Inc. All rights reserved.

Glossary

CYP Nomenclature for the enzymes of the cytochrome P-450 superfamily.

Cytochrome P-450 Hemoprotein showing an unusual absorption of the reduced CO complex at 450 nm.

Genetic polymorphism Inherited deficiencies of single enzymes such as CYP2D6 and CYP2C19.

Glucocorticoids Steroid hormones regulating glucose metabolism, regulating the stress response of the body, and suppressing inflammation.

Hormone Chemical messenger secreted into the circulating blood.

Mineralocorticoids Steroid hormones regulating the salt and water levels of the body and in this way the blood pressure.

Cytochromes P-450 are ubiquitously distributed multicatalysts, which were discovered approximately 50 years ago. They possess a high degree of complexity and display a broad field of activity. Although already more than 18 000 different P450 genes have been described, new forms are constantly being found, opening up new research fields. They are the key enzymes responsible for the metabolism of many drugs, carcinogens, alkaloids, pesticides, and other important xenobiotics. Moreover, they are involved in a variety of physiological processes such as steroid hormone, eicosanoid, vitamin D, and bile acid biosynthesis. Cytochromes P-450 are hemoproteins that use molecular oxygen to catalyze various reactions. In most cases, they get the electrons necessary for oxygen activation and substrate hydroxylation from NADH (the reduced form of nicotinamide adenine dinucleotide (NAD)) or NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate (NADP⁺)), in general via the action of electron-transferring proteins. Most eukaryotic cytochromes P-450 are membrane bound. Many of them are inducible, but some are constitutively expressed. Defects in some of the mammalian cytochromes P-450 lead to pathological effects, such as congenital adrenal hyperplasia and hypertension, and adverse drug effects.

Cytochrome P-450 – General Aspects

There are two general classes of enzymes involved in oxygen metabolism: oxidases, transferring electrons from a substrate to oxygen, and oxygenases, transferring oxygen to a substrate after reductive splitting of molecular oxygen. Oxygenases can be divided into dioxygenases and monooxygenases. Monooxygenases (mixed-function oxidases) catalyze the incorporation of a single atom of molecular oxygen into a substrate with the concomitant reduction of the other atom to water. The monooxygenases are divided into two classes, the internal and the external monooxygenases. Internal monooxygenases extract two reducing equivalents from the substrate to reduce one atom of dioxygen to water, whereas external monooxygenases use an external reductant. Cytochromes P-450 are external monooxygenases. Initially the microsomal drug and xenobiotic-metabolizing enzymes were referred to as mixed-function oxidases, but in more recent years the term monooxygenase has become the more accepted one.

Cytochromes P-450 got their name from their character as a hemoprotein and from their unusual spectral properties, displaying a typical absorption maximum of the reduced CO-bound complex at 450 nm (**Figure 1**) – cytochrome stands for a hemoprotein, P for pigment, and 450 reflects the absorption peak of the reduced CO-bound complex at 450 nm. The ability of reduced P450 to produce an absorption peak at 450 nm upon CO binding is still used for the estimation of P450 content. The red shift of approximately 30 nm observed in cytochromes P-450 means that the distribution of electron density at the heme is significantly perturbed compared to other cytochromes. It has been documented that it is the thiolate sulfur that causes this effect by means of a direct bond to the iron. The Soret band (named after its discoverer) describes the absorption band of hemoproteins at approximately 380–420 nm.

In general, cytochrome P-450 systems catalyze the following reaction:

They catalyze reactions as diverse as hydroxylation; N-, O-, and S-dealkylation; sulfoxidation; epoxidation; deamination; desulfuration; dehalogenation; peroxidation; and N-oxide reduction. Their substrates include fatty acids, steroids, and prostaglandins, as well as a multitude of foreign compounds such as drugs, anesthetics, organic solvents, ethanol, alkylaryl hydrocarbon products, pesticides, and carcinogens. This diversity of catalyzed reactions and acceptable substrates has attracted researchers from diverse fields to the study of cytochrome P-450 systems (**Figure 2**). In addition to pharmacologists and toxicologists, endocrinologists, physiologists, microbiologists, organic chemists, plant biologists, and environmental scientists also are working on diverse aspects of P450 function and regulation.

It is obvious that this diversity of substrates and catalyzed reactions cannot be managed by only a few different isoforms. In the human genome alone 57 different P450 genes have been found, and in total more than 18 000 different P450 genes have been described (D. Nelson lists the available P450 sequences identified so far on his website). This superfamily of proteins (and their respective genes) is divided into families, subfamilies, and finally into individual members according to

similarities in primary structure. A new nomenclature has been introduced in which CYP and a series of numbers and letters are used to characterize each P450 as a hemoprotein. For example, in CYP1A1, for cytochrome P4501A1 (previously called P450c), the first Arabic number defines the gene family, the following letter defines the subfamily, and the second number defines the individual enzyme. Members of the same gene family are defined as usually having >40% sequence identity to a P450 protein from any other family. Mammalian sequences within the same subfamily are always >55% identical. The numbers of individual P450 enzymes in different species differ, the highest numbers observed so far being in plants.

Figure 1 CO-difference spectrum of reduced vs. oxidized cytochrome P-450 (CYP106A2).

Structural Organization of Cytochrome P-450 Systems

As already mentioned, cytochromes P-450 belong to the external monooxygenases. This means that they need an external electron donor to transfer the electrons necessary for oxygen activation and the following substrate hydroxylation. Although a very high variety of the electron supporting systems has been found, two main classes of cytochromes P-450 can be defined with respect to their electron-supporting system: the microsomal type and the mitochondrial/bacterial type (Figure 3).

Microsomal cytochromes P-450 are membrane bound and accept electrons from a microsomal NADPH-cytochrome P-450 reductase, containing flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). All drug- and xenobiotic-metabolizing cytochromes P-450 isolated so far belong to this class. In addition, CYP102 (P450BM-3) isolated from *Bacillus megaterium* was shown to belong to this class. This P450 system consists of a polypeptide chain with two different domains, one containing the hemoprotein and the other one containing a flavoprotein with FAD and FMN. Many of the other bacterial cytochromes P-450 belong to the second class. They are soluble and obtain the electrons necessary for the reaction mechanism from an NADH-dependent FAD-containing reductase via an iron-sulfur protein of the [2Fe-2S] type. Other bacterial P450s accept electrons from a variety of other partners.

Mitochondrial cytochromes P450, which are involved, for example, in the side-chain cleavage of cholesterol, the 11 β -hydroxylation of deoxycortisol, and the production of aldosterone, also belong to the second class. These cytochromes P-450 are localized in the inner mitochondrial membrane, where the [2Fe-2S] protein, called adrenodoxin in the case of adrenal steroid hydroxylase systems, is a soluble protein of the matrix. The FAD-containing reductase, adrenodoxin reductase, is associated with the inner mitochondrial membrane.

Figure 2 Cytochrome P-450 research and application fields.

Figure 3 Model for the organization of the two main classes of cytochrome P-450 systems. (a) Microsomal type. (b) Mitochondrial/bacterial type.

The interaction of the cytochromes P-450 with their corresponding electron donors is a necessary prerequisite of the catalytic cycle. Its specificity guarantees a sufficient reaction rate of catalysis and likewise a discrimination between the different potential donors and acceptors of electrons to protect the system from shunt reactions.

Because many different isoenzymes in liver microsomes have to interact with only one type of reductase, the binding site for reductase is very similar or identical on various cytochromes P-450. Salt bridges are responsible for the recognition of reductase by the cytochromes P-450 and for the correct orientation of the proteins to one another. In addition to microsomal reductase, some microsomal cytochromes P-450 are able to accept the second electron from cytochrome b5. Cytochrome b5 has also been shown to exert a differential stimulatory action, depending on the form of cytochrome P-450 and the substrate metabolized.

In mitochondrial steroid hydroxylases and in the camphor hydroxylating bacterial cytochrome P-450 (CYP101) system, a charge-pair interaction mechanism has been demonstrated by

chemical modification, site-directed mutagenesis studies, and structural data of electron-transfer complexes. Like microsomal reductase, the mitochondrial ferredoxin has been shown to deliver electrons to different cytochromes P-450. From the available data, a shuttle model is favored, in which the oxidized ferredoxin interacts first with the ferredoxin reductase to undergo reduction, with the formation of an $\text{Fe}^{3+}-\text{Fe}^{2+}$ iron-sulfur cluster. It dissociates from the reductase and then interacts with the respective cytochrome P-450, to which it delivers this electron before going back to the reductase, and transferring the second electron to the cytochrome P-450. The mechanism of electron transfer between the components of the different cytochrome P-450 systems, one of the fundamental problems in life sciences, is not well understood.

Reaction Cycle

The generally accepted mechanism of cytochrome P-450-dependent substrate conversion is depicted in the overall

scheme presented in Figure 4. The first step of the reaction cycle is the formation of the substrate–enzyme complex. Substrate binding induces structural changes in the cytochrome P-450 that may result not only in a spin shift, but also in changes of the redox potential and in changed binding affinities between interacting components of the cytochrome P-450 system. The second step of the reaction cycle is the introduction of the first electron, either by NADPH-dependent reductase or via a ferredoxin (see Figure 3). Iron ($3+$) is reduced to iron ($2+$). Although in some cytochromes P450 the substrate binding is a prerequisite for electron transfer, this is not a universal requirement. In the third step of the reaction cycle, the hemo-protein reduced by one electron binds the dioxygen molecule. As shown in Figure 4, from this complex a superoxide anion radical can be released. Step 4 of the reaction cycle is the introduction of the second electron. In some instances, another microsomal hemoprotein, cytochrome b_5 , can facilitate catalysis by providing the second electron. From the $(\text{RH})\text{Fe}^{3+}(\text{O}_2^{2-})$ complex, hydrogen peroxide can be split off. The structure of the activated oxygen complex and the precise mechanism of oxygen cleavage are not fully understood yet. Step 5 in the reaction cycle is the removal of the terminal oxygen atom from the dioxygen ligand, that is, the cleavage of the dioxygen bond. Heterolysis of the oxygen–oxygen bond also results in the formation of a putative oxyferryl species. Heterolytic cleavage in P450cam (CYP101), where most of the mechanistic studies have been performed, was shown to be facilitated by hydrogen bonding of the ferric hydroperoxide via a water molecule to a highly conserved threonine residue (Thr252 in CYP101), which is involved in a proton transfer network that promotes oxygen cleavage. The introduction of two electrons and two protons to the putative oxyferryl species may lead to the formation of water. Finally, in step 6 the hydroxylated product dissociates and the cycle can start again. Interestingly, in many but not all cytochromes P450 a shunt reaction can proceed (step 7), in which the substrate can be hydroxylated directly by peroxides such as hydrogen peroxide, cumene

hydroperoxide, and *tert*-butyl hydroperoxide without the necessity of an interaction with an electron-donating system. Taken together, cytochromes P-450 do not catalyze just monooxygenase, but also oxidase and peroxidase reactions. Variations of this scheme for the reaction mechanism of cytochromes P-450 occur with different cytochrome P-450 systems such as thromboxane and prostacyclin synthase, nitric oxide reductase (CYP55A1), and others.

Regulation of Cytochrome P-450 Systems

The regulation of enzyme systems is possible at different levels. When considering cytochrome P-450 systems, the complexity of the reaction cycle, the organization within membrane systems for most of the eukaryotic cytochromes P450, and their organ- and tissue-specific expression imply various possible ways for regulatory mechanisms to work. Interaction between these mechanisms then leads to the tuned response of these enzyme systems to endogenous and exogenous signals in terms of acute and long-term reactivities of cytochromes P450.

First, it is possible to regulate cytochromes P-450 on the level of the organism. Some of the cytochromes P-450 are expressed in age-, tissue-, and sex-dependent manners. These differences in the expression pattern are governed by sex or other hormones. There are also clearly developmental influences on the expression and function of various cytochrome P-450 systems.

Cellular regulation of cytochromes P-450 is extremely complex and can occur on at least two different levels, enzyme induction and posttranslational modification of enzymes. The induction of drug-metabolizing enzymes was noted in the early 1950s. Since then specific inducers for various cytochrome P-450 families and subfamilies have been identified. It can be demonstrated that the inducer functions by enhancing the rate of messenger RNA (mRNA) synthesis of a special cytochrome P450. In some cases, receptors (the best-studied

Figure 4 Reaction cycle of cytochromes P450.

system currently is the aryl hydrocarbon, Ah, receptor) are involved in mediating the effect of the inducer. Not all cytochromes P450 are, however, inducible; some of them are constitutively expressed. Moreover, regulation on the epigenetic level and by microRNA has been described for several P450s.

After the biosynthesis of cytochromes P450, the enzymes might be subject to posttranslational modifications to exert a short-term control of activity. One of the most common types of posttranslational modifications in eukaryotic organisms is protein phosphorylation, which has been demonstrated for several steroid hydroxylases such as the microsomal CYP7 and the mitochondrial CYP11A1 and also for the drug-metabolizing microsomal CYP2B4.

Because nearly all the eukaryotic cytochromes P-450 are bound to membranes, they can be regulated also at that level. By contrast, most of the bacterial cytochromes P450, such as CYP101, CYP102, and CYP108 are soluble. The composition of the membrane (e.g., protein–lipid as well as lipid-mediated protein–protein interactions) exerts a functional control on cytochromes P450. Lipids appear to function in at least three ways – they (1) stabilize and induce a functionally active conformation of cytochromes P-450 and the corresponding electron-transfer systems, (2) modulate the electron transfer, and (3) mediate interactions between cytochromes P-450 and the electron-donor systems.

Finally, cytochromes P-450 can be regulated at the molecular level. This includes regulation of the activities by changes of the primary sequence (e.g., by polymorphisms), the spin equilibrium, protein–electron donor interactions, and protein–protein interactions.

Important Functions of Cytochrome P-450 Systems

Cytochromes P-450 and Drug Metabolism

Cytochromes P-450 are able to perform the biotransformation of an enormous variety of substrates. Taking into account all drugs metabolized by enzymes, cytochromes P-450 are responsible for more than two-thirds of these reactions. The most important cytochrome P-450 form for biotransformation in humans is CYP3A4; it is involved in the metabolism of more than one-half of the known drugs and xenobiotics, such as nifedipine, cyclosporin, erythromycin, gestodene, and aflatoxins. This variety of substrates makes CYP3A4 one of the most important enzymes for drug metabolism. The fact that a single cytochrome P-450 is responsible for the metabolism of many different drugs may lead to competition among various drugs for the same enzyme and thus to drug–drug interactions, resulting in higher plasma levels of the less successful (i.e., displaying a lower affinity for the particular cytochrome P450) substrate and even to fatal side effects of the drug treatment.

Another fact complicating drug treatment is the presence of genetic polymorphisms in some of the drug-metabolizing enzymes. It has been shown that 5–10% of Caucasians suffer from a decreased ability to metabolize certain drugs such as debrisoquine and bufuralol (i.e., they are poor metabolizers), due to the presence of nonfunctional alleles of CYP2D6 in these individuals. A smaller portion of patients metabolize the corresponding drugs extremely rapidly (i.e., they are extensive metabolizers) due to having multiple copies of this

gene. These pharmacogenetic effects are being studied in many laboratories and will certainly lead to personalized pharmacotherapy.

Physiological Role of Cytochromes P450

In addition to being involved in drug metabolism and xenobiotica degradation, cytochromes P-450 also play a pivotal role in various physiological processes in humans. They are central in the biosynthesis of steroid hormones (sex hormones, glucocorticoids, and mineralocorticoids), vitamin D, retinoic acid, fatty acids, bile acids, and eicosanoids. Some severe defects are connected to mutations in cytochrome P-450 genes, such as congenital adrenal hyperplasia, which is mostly due to a steroid 21-hydroxylase (CYP21) deficiency. In addition, human essential hypertension can be caused by the overproduction of aldosterone produced by CYP11B2. More recently, products of cytochrome P-450 reactions, such as oxysterols and the endothelium-derived hyperpolarizing factor (EDHF), have been found to play important roles in cellular cholesterol homeostasis, inhibition of cellular proliferation, gene regulation, endothelium-dependent dilation, and enhanced endothelial cell proliferation.

Cytochromes P450 as Drug Targets

While fungal P450s are long established, successful targets in antimycotic therapy, there is increasing evidence that a variety of human P450s can also serve as valuable therapeutic targets. Only ~300 human-genome-derived proteins are used as targets so far, including several P450 forms. Well-known drug targets are the steroidogenic P450s. CYP19A1 catalyzing the aromatization of the steroid A ring represents a target of blockbuster drugs, especially against breast cancer. More recently, CYP11B2 catalyzing the last steps in aldosterone formation became a target for the development of drugs against hypertension and congestive heart failure. Moreover, the differential expression of various P450s in tumors opens up the possibility to use prodrugs leading after their biotransformation to selective toxicity exclusively in these cells.

Cytochrome P-450 Diversity

Cytochromes P-450 are found in all kingdoms – eubacteria, archaeobacteria, fungi, plants, fish, insects, and vertebrates. About 250 different forms have been found in the plant *Arabidopsis thaliana*. It was shown that plant cytochromes P450 play a role in the metabolism of a variety of secondary metabolites, in plant–insect interaction, in herbicide metabolism, and in other vital functions. Due to the diversity of catalyzed reactions, it can be anticipated that plant cytochromes P450 will offer a broad field for future applications.

Cytochromes P450 and Their Biotechnological Application

The interesting chemistry and the high regio- and stereoselectivity of hydroxylation reactions catalyzed by cytochromes

P450 opens up new potentials for practical application of these systems. So far, industrial application is, however, focused on only very few cases due to the complexity of these protein systems. The most prominent example is the production of transgenic plants displaying changed blossom colors (purple carnations and blue roses). The other example is the production of hydrocortisone using a designed strain of Baker's yeast expressing a total of four P450s and engineering 13 proteins.

More recently, site-directed mutagenesis and directed evolution of different P450s has been used to produce valuable drug metabolites and fine chemicals.

Furthermore, the diversity of P450s becoming available through the sequencing of genomes of a variety of organisms opens up new sources for application.

Glossary

Apoptosis Programmed cell death.

Chemokine Chemotactic cytokines that mediate the tissue localization of immune, inflammatory, vascular and cancer cells.

Cytokine Small protein intercellular messengers that mediate key biological functions.

Interleukin Cytokines that were initially thought to solely mediate signaling between leukocytes, but have since been recognized to be produced and act on a variety of cell types.

Trans-signaling The ability of soluble cytokine receptor to function as an agonist and mediate signaling by cells that do not express the receptor.

Cytokines are small protein intercellular messengers that mediate key biologic functions related to inflammation, host defense, tumor surveillance, and innate and adoptive immune responses. Efforts to identify a soluble factor produced by leukocytes that functions as an endogenous pyrogen led to the discovery of the first cytokine, named ‘interleukin-1 (IL-1)’, which was purified in 1977 and cloned in 1984. Although interleukins were initially thought to solely mediate signaling between leukocytes, it has since been recognized that they can be produced and act upon a variety of cell types. Multiple additional classes of cytokines have since been identified, which include the tumor necrosis factor superfamily, chemokines, and the transforming growth factor family.

Interleukins

Significant progress has been made in interleukin biology since the discovery of IL-1. There are currently 37 named interleukins to which functions have been identified, with one additional interleukin yet to be named. Interleukins can be grouped into several families that are discussed below.

IL-1 Family

The IL-1 family is comprised of 11 members, which include IL-1 α (IL-1 F1), IL-1 β (IL-1 F2), IL-1 receptor antagonist (IL-1Ra, IL-1 F3), IL-18 (IL-1 F4), IL-33 (IL-1 F11), IL-36 α (IL-1 F6), IL-36 β (IL-1 F8), IL-36 γ (IL-1 F9), IL-36 receptor antagonist (IL-36Ra, IL-1 F5), IL-37 (IL-1 F7), and IL-38 (IL-1 F10). Activation of IL-1 family members is highly regulated and coordinated to prevent excessive inflammatory responses. IL-1 β and IL-18 are synthesized as inactive proforms that are activated following cleavage of their pro-domains by the cysteine protease, caspase-1. Caspase-1 functions within the context of molecular platforms, called ‘inflammasomes’, which are pattern-recognition receptors that sense exogenous and endogenous danger signals, such as pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs). Activation of the NLRP3 inflammasome results in the clustering and activation of caspase-1. Activated

caspase-1 cleaves the proforms of IL-1 β and IL-18 to generate mature, secreted pro-inflammatory interleukins that play key roles in cellular responses to infection and injury.

The IL-1 receptor family is similarly comprised of 11 members that are characterized by extracellular immunoglobulin domains and an intracellular toll-IL-1 receptor (TIR) domain that interacts with adaptor proteins to mediate signaling. For example, both IL-1 α and IL-1 β can bind the type I IL-1 receptor (IL-1R1), which then recruits the IL-1 receptor accessory protein, IL-1RAcP, to function as a co-receptor chain (Figure 1). This facilitates the recruitment of myeloid differentiation primary response protein 88 (MyD88) via a TIR domain interaction, as well as IL-1R-associated kinase 4 (IRAK4), and IRAK1 or IRAK2, which form the Myddosome complex. Activated IRAK1 then dissociates from the Myddosome complex to activate tumor necrosis factor receptor (TNFR)-associated factor 6 (TRAF6), which signals via downstream pathways, such as nuclear factor- κ B (NF- κ B) and mitogen-activated protein (MAP) kinases.

IL-18 signals via binding to IL-18R α , which recruits the co-receptor, IL-18R β , to induce signaling. IL-18 binding protein (IL-18BP), which is distantly related to the IL-1 receptor family, is a soluble protein that binds and sequesters IL-18, thereby preventing activation of cellular IL-18 receptors. ST2 (IL-33R α and IL-1RL1), the receptor for IL-33, and IL-1Rrp2 (IL-1RL2), which is the receptor for IL-36 α (IL-1 F6), IL-36 β (IL-1 F8), and IL-36 γ (IL-1 F9), also recruit the shared receptor subunit IL-1RAcP to activate downstream signaling pathways. The receptors for IL-37 (IL-1 F7) and IL-38 (IL-1 F10) have yet to be identified. In addition to binding and signaling via cell-surface receptors, the pro-forms of IL-1 α and IL-33 can translocate to the nucleus and thereby modulate gene transcription.

Multiple layers of regulation exist to prevent excessive or undesired IL-1 signaling. IL-1 receptor antagonist (IL-1Ra) avidly binds IL-1R1 without recruiting IL-1RAcP and thereby antagonizes the activity of IL-1 β and IL-1 α . IL-1RII functions as a decoy receptor that binds IL-1 β with greater affinity than IL-1R1, but has a short cytoplasmic domain that does not bind Myd88 and therefore does not signal. IL-1RII can also recruit and sequester IL-1RAcP to attenuate IL-1 signaling. IL-36 receptor antagonist (IL-36Ra) binds IL-1Rrp2, but does

Figure 1 Interleukin 1 signaling.

not mediate the recruitment of IL-1RAcP and thereby functions as a receptor antagonist that attenuates the biological activity of IL-36 α , IL-36 β , and IL-36 γ . A soluble form of ST2 that binds and inhibits IL-33 activity can be generated by alternative messenger RNA (mRNA) splicing. Lastly, single immunoglobulin IL-1R-related (SIGIRR) molecule or TIR8 is an IL-1 receptor family member expressed by epithelial cells that does not signal due to the absence of a functional TIR domain and thereby attenuates signaling by IL-1, IL-18, and IL-33.

IL-1 family members play key roles in inflammation. Administration of a recombinant IL-1RA has been used clinically to successfully attenuate the manifestations of auto-inflammatory syndromes characterized by excessive IL-1 signaling, such as familial cold auto-inflammatory syndrome (FCAS), neonatal-onset multisystem inflammatory disease (NOMID), and Muckle-Wells syndrome (MWS). These auto-inflammatory syndromes are caused by mutations in the cryopyrin or NALP3 genes that result in spontaneous inflammasome formation and increased IL-1 β secretion. IL-1 may also play a role in the pathogenesis of gout due to inflammasome activation by uric acid crystals, as well as in type II diabetes mellitus and ischemia-induced inflammation. IL-18, which was initially cloned as an interferon-gamma-inducing factor that augments natural killer cell activity, promotes Th1 responses and is synthesized by macrophages, dendritic cells, epithelial cells, and keratinocytes.

Figure 2 Interleukin 6 signaling.

By contrast, IL-33 promotes Th2 responses and has been implicated in the pathogenesis of asthma and atopic dermatitis.

IL-6 Family

The IL-6 family, which are class I cytokines (see below), is comprised of IL-6, IL-11, IL-27, IL-31, ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), cardiotrophin-like cytokine (CLC), leukemia inhibitory factor (LIF), neuropoietin (NPN), and oncostatin M (OSM). IL-6 was initially identified in 1986 as a B-cell stimulatory factor that promotes immunoglobulin G (IgG) production. IL-6 is a pro-inflammatory cytokine with pleiotropic biologic functions that include the regulation of immune and inflammatory responses, as well as the modulation of neoplasia, metabolism, regeneration, and neuronal signaling. Furthermore, IL-6 has been implicated in the pathogenesis of rheumatoid arthritis, multiple sclerosis, asthma, diabetes, inflammatory bowel disease, and colitis-associated colon cancer. IL-6 is produced by a diverse variety of cells, with macrophages, fibroblasts, and endothelial cells representing the main cellular sources.

IL-6 and IL-11 bind to IL-6R α and IL-11R α , respectively, which then associate with gp130 homodimers (**Figure 2**). All IL-6 family members, except for IL-31, signal via receptors that contain glycoprotein 130 (gp130) as a common subunit. The gp130 subunit does not possess intrinsic kinase activity, but instead noncovalently associates with janus kinases (JAK1, JAK2, and TYK2) which undergo autophosphorylation and activation upon ligand binding, with subsequent activation of signal transducer and activator of transcription (STAT) transcription factors, STAT3 or STAT1. IL-6 can also activate the transcription factor CAAT-enhancer-binding protein (C/EBP), as well as signal via mitogen-activated protein kinases (MAPKs). LIF, CNTF, OSM, CT-1, NPN, and NNT-1 signal via

complexes comprised of the LIF receptor (LIFR) and gp130. IL-27 signals via the IL-27 receptor alpha chain (IL-27RA and WSX1) and gp130, while OSM signals via a complex comprised of the OSM receptor (OSMR) and gp130. By contrast, gp130 is not necessary for IL-31 signaling which occurs via the OSMR and the gp130-like receptor.

IL-6 can also activate cells that do not express IL-6R via a process called 'trans-signaling'. This occurs via an interaction between membrane-bound gp130, which is expressed on most cells, and a soluble form of IL-6R that binds soluble IL-6. Thus, in contrast to soluble forms of most receptors that are antagonists, soluble IL-6 receptors serve as agonists.

IL-10 Family

The IL-10 family is comprised of six members, which include IL-10, IL-19, IL-20, IL-22, IL-24, and IL-26. There are also four viral homologs produced by the Epstein-Barr virus, the equine herpesvirus type 2, Orf parapoxvirus, and simian cytomegalovirus. In addition, there are three IL-10 family members that are classified as type III interferons, IL-28 α (IFN- λ 1), IL-28 β (IFN- λ 2), and IL-29 (IFN- λ 3). Despite weak sequence identity, IL-10 family members share significant structural similarity and are characterized by a compact, bundle-like shape that is comprised of six or seven α -helices. The IL-10 protein exists as a homodimer, whereas IL-19 and IL-22 are monomers. IL-10 is primarily produced by activated monocytes and T cells to suppress inflammatory and immune responses.

IL-10 members belong to the class II cytokine family and bind class II cytokine receptors that lack a WSXWS motif in the extracellular domain. IL-10 receptors exist as heterodimers, comprised of a R1 and an R2 chain, which are shared by IL-10 family members. The receptor for IL-10 is comprised of IL-10R1, which is specific for IL-10, and IL-10R2, which is shared by IL-22, IL-26, IL-28 α , IL-28 β , and IL-29 (Figure 3). The type I IL-20 receptor, which is comprised of IL-20R1 and IL-20R2, binds IL-19, IL-20, and IL-24, whereas the type II IL-20 receptor, which is comprised of IL-22R1 and IL-20R2, binds IL-20 and IL-24. The IL-22 receptor is comprised of IL-22R1 and IL-10R2, while IL-26 binds to a heterodimeric receptor comprised of IL-20R1 and IL-10R2. In addition, there is a naturally occurring soluble receptor, IL-22 binding protein (IL-22BP), which binds and neutralizes the biological activity of IL-22.

IL-10 receptor family members do not have intrinsic receptor tyrosine kinase activity, but instead signal via the JAK-STAT pathway, with Jak1 binding to IL-10R1 and IL-22R1, while Tyk2 binds IL-10R2. This leads to the activation of STAT3, whereas STAT1 and STAT5 may also be activated in specific cell types. IL-10 family members can also activate MAPK signaling pathways.

IL-17 Family

The IL-17 family is a recently identified family of cytokines that plays important roles in inflammation and immune responses. IL-17A, the founding member of the IL-17 family, is produced primarily by T helper 17 (Th17) cells, which are a subset of CD4⁺ T cells that regulate allergic disorders, such as asthma, and autoimmune disorders, such as rheumatoid arthritis, multiple sclerosis, psoriasis, and inflammatory bowel disease.

Figure 3 Interleukin 10 signaling.

IL-17A also participates in host defense against bacterial and fungal infections, as well as in granulopoiesis. $\gamma\delta$ T cells also express IL-17A. IL-17A and IL-17 F exist either as homodimers or as heterodimers. Four additional IL-17 family members have been identified, IL-17B, IL-17 C, IL-17D, and IL-17E (also known as IL-25). IL-17 F is primarily involved in mucosal host defense, whereas IL-17E (IL-25) amplifies immune responses by Th2 cells.

The five members of the IL-17 receptor family include IL-17RA, IL-17RB, IL-17RC, IL-17RD, and IL-17RE. The IL-17 receptor is a heterodimer comprised of IL-17RA and IL-17RC that bind homodimers of IL-17A or IL-17 F, as well as IL-17A/IL-17 F heterodimers (Figure 4). Biological effects of IL-17A and IL-17 F may be regulated at the level of receptor binding, as IL-17A has higher affinity for IL-17RA, while IL-17 F has a higher affinity for IL-17RC. Furthermore, cellular patterns of expression differ for these receptors, as IL-17RA is primarily expressed by immune cells, whereas IL-17RC is primarily expressed by nonimmune cells. Homodimeric IL-17E (IL-25) signals via the IL-25 receptor, which is comprised of IL-17RA and IL-17RB. IL-17RB and IL-17RE are the receptors for IL-17B and IL-17C, respectively. The receptor for IL-17D has not been identified nor has the ligand for IL-17RD.

The IL-17 receptor signals via the recruitment of the adaptor protein Act1 (TRAF3IP3 and CIKS), which directly associates with IL-17RA and IL-17RC via a SEFIR (SEF/IL-17R) domain interaction. This recruits TRAF6 and TAK1, leading to the activation of NF- κ B, as well as MAPKs and transcription factors, AP-1 and C/EBP. TRAF3 can also associate with Act1 and negatively regulate IL-17A-mediated activation of NF- κ B and MAPK. Binding of IL-17E (IL-25) to the IL-25R, which is a

Figure 4 Interleukin 17 signaling.

heterodimer of IL-17RA and IL-17RB, also signals via the recruitment of Act1, TRAF6, and TAK1.

Type I Cytokines

Type I cytokines, which have a three-dimensional structure comprised of four α -helical bundles, can be divided into subgroups characterized by short chains of approximately 15 amino acids, or long chains of 25 amino acids. Short-chain type I cytokines can be further subdivided based upon whether they share common receptor subunits of multimeric type I cytokine receptors. For example, type I cytokines whose receptors share the common cytokine receptor γ -chain (γ_c) include, IL-2, IL-4, IL-7, IL-9, IL-13, IL-15, IL-21, and thymic stromal lymphopoietin (TSLP), whereas those that share the common cytokine receptor β -chain (β_c) include IL-3, IL-5, and granulocyte macrophage colony-stimulating factor (GM-CSF). Receptors for type I cytokine family members, as well as type II cytokines, do not possess intrinsic tyrosine kinase activity, but instead signal via the JAK/STAT pathway. Additional short-chain type I cytokines include macrophage-colony stimulating factor (M-CSF) and stem cell factor (SCF). Cytokines that share the common γ_c receptor activate JAK1, JAK2, JAK3, and TYK2, which leads to the downstream activation of STAT3, STAT5A, STAT5B, or STAT6 (Figure 5). By contrast, cytokines that share the common β_c receptor signal via JAK2 and STAT5A and STAT5B. Long-chain type I cytokines are typified by the IL-6 family that signal via receptors that share gp130. Additional long-chain type I cytokines include IL-12, growth hormone, prolactin, erythropoietin, thrombopoietin, leptin, and granulocyte colony-stimulating factor (G-CSF).

The importance of class I cytokines is evidenced by the role of the common cytokine receptor γ -chain (γ_c) in T-cell development. X-linked severe combined immunodeficiency (SCID) occurs in individuals with mutations in the γ_c chain that results in the absence of T cells and natural killer (NKT) cells, as well as nonfunctional B cells. Patients with SCID typically die in their first year if they do not undergo bone marrow transplantation. An autosomal mutation in JAK3 can also cause SCID as a result of defective signaling via the γ_c receptor. JAK1- and JAK2-deficient mice display perinatal or fetal lethality, which may reflect their effects in humans.

Type II Cytokines

Type II cytokines are comprised of interferons (IFN- α/β and IFN- γ) and IL-10 family members (see above). IFNs play key roles in host defense against DNA and RNA viruses, as well as tumor cells. IFNs also modulate innate and adaptive immune responses, as well as autoimmunity. Type I IFNs are comprised of 13 IFN- α genes, as well as single genes for IFN- β , IFN- ω , IFN- ϵ , and IFN- κ . Type I IFNs are nonglycosylated proteins of 165–200 amino acids which contain five α -helical bundles that are positioned by two disulphide bonds. IFN gene transcription is initiated via toll-like receptor signaling. For example, binding of double-stranded RNA to TLR3 or cytoplasmic RNA helicases (retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein 5 (MDA5)) activates IFN regulatory factors, IRF3 and IRF7, as well as NF- κ B, with resultant transcription of type I IFNs. The type I IFNs then bind a heterodimeric receptor comprised of IFN receptor 1 (IFNAR1) and IFN receptor 2 (IFNAR2), which are associated with TYK2 and JAK1 (Figure 6). This induces the

Figure 5 Interleukin 2 signaling.

phosphorylation of STAT1 and STAT2 to form a heterotrimeric complex with IRF9 that binds IFN-stimulated response elements (ISREs) in the promoters of IFN- α -activated genes.

IFN- γ is a type II IFN that is expressed by NKT cells and activated T cells. The IFN- γ protein is a single glycosylated protein of 140 amino acids that exists as an antiparallel homodimer that binds to a receptor complex comprised of the IFN- γ receptor 1 (IFNGR1) and IFN- γ receptor 2 (IFNGR2). IFN- γ binds to two IFNGR1 receptor chains, which are stabilized by two IFNGR2 chains (Figure 7). IFNGR1 binds JAK1, whereas IFNGR2 binds JAK2, which leads to the activation of a STAT1 homodimer that binds to IFN- γ -activated sites (GAS) to induce the transcriptional activation of IFN- γ -activated genes.

Type III IFNs (IFN- λ) are members of the IL-10 cytokine family (see above) and signal via a heterodimeric receptor comprised of the IL10R2 (IL-10RB) and IFN- λ receptor 1 (IFNLR1 or IL28RA), which activates the same pathway as type I IFNs.

Tumor Necrosis Factor Family

The tumor necrosis factor (TNF) family is a large family of at least 17 members that play key roles in inflammation and immunity, as well as a broad range of diverse biological functions, including host defense, neoplasia, tissue modeling and

Figure 6 Interferon- α signaling.

remodeling, and neuronal development. TNF ligands exist as type 2 membrane proteins that have both a membrane-associated pro-form, as well as a cleaved, soluble mature form. The TNF receptor family is similarly large, with at least 27 members that exist as type I membrane proteins.

TNF, the prototypical member of the TNF superfamily, was originally recognized as the immune cell product that induces tumor cell cytotoxicity and necrosis. TNF was cloned in 1984 and found to mediate pleiotropic biologic functions that include tumor cell apoptosis, inflammation, immune cell function, host defense, autoimmunity, and organ development. TNF exists as a stable homotrimer of type II transmembrane proteins that undergoes proteolytic cleavage by ADAM17 (TNF- α converting enzyme (TACE)) to release a soluble form comprised of three 17-kDa protomers. TNF binds to two receptors, the type 1 TNF receptor (TNFR1 and CD120a) and the type 2 TNF receptor (TNFR2 and CD120b). TNFR1 and TNFR2 exist as homotrimers that are pre-assembled via preligand binding assembly domains.

TNFR1 can activate signaling pathways that have opposite outcomes and promote either inflammation or apoptosis. The pro-inflammatory/anti-apoptotic pathway is mediated via recruitment of signaling complex I, which consists of TNF receptor-associated protein with a death domain (TRADD), receptor interacting protein (RIP), cellular inhibitor of apoptosis proteins 1 and 2 (cIAP1/2), and TNF receptor-associated factor 2 (TRAF2) (Figure 8). This occurs following TNF-induced translocation of TNFR1 to lipid rafts and is associated with the ubiquitination of TNFR1, TRAF2, and RIP1. This leads to the recruitment of the I κ B kinase

Figure 7 Interferon- γ signaling.

Figure 8 Tumor necrosis factor (TNF) signaling.

(IKK) complex and the IKK-activating complex, comprised of TAK1, TAB2, and TAB3, with the resultant activation of NF- κ B, which has pro-inflammatory and anti-apoptotic effects. Signaling complex 1 can also activate p38 MAPK and JNK kinases. Activation of pro-apoptotic pathways occurs when RIP and TRADD dissociate from the TNFR1 complex at the plasma membrane and recruit Fas-activated via death domain (FADD), TNFRSF6) and pro-caspase 8 to form signaling complex 2. When NF- κ B is activated by signaling complex 1, the caspase-8 inhibitor, cellular FLICE inhibitory protein long (cFLIP_L) is recruited to signaling complex 2, leading to cell survival. In the absence of NF- κ B activation, pro-caspase 10 is recruited to signaling complex 2, which results in programmed cell death.

Several lines of evidence support the key role of TNF in the regulation of inflammation. First, TNF receptor-associated periodic syndrome (TRAPS) is an auto-inflammatory disorder characterized by recurrent episodes of fever, myalgia, rash, abdominal pain, and conjunctivitis that is caused by missense mutations in TNFR1 (TNFRSF1A). The TRAP-associated TNFR1 mutations lead to the intracellular accumulation of mutant TNFR1 molecules that do not signal, but instead display enhanced secretion of pro-inflammatory cytokines in response to lipopolysaccharide. Second, TNF inhibitors have entered clinical use for the treatment of inflammatory arthritides, such as rheumatoid arthritis. Third, TNF blockade has been associated with opportunistic infections, such as tuberculosis, which illustrates the important role of TNF in host defense against bacterial, fungal, parasitic, and mycobacterial infections.

Chemokines

Chemokines are chemotactic cytokines that mediate the tissue localization of immune, inflammatory, vascular, and cancer cells. Chemokines constitute the largest cytokine family in humans, with 44 different chemokine genes. Of note, the largest number of chemokine genes is present in the zebrafish genome,

which contains more than 100. Chemokine ligands, which have four conserved cysteines, are grouped into five subfamilies based upon the location of the two amino-terminal cysteines. The conserved cysteines form two intra-chain disulfide bonds that link cysteine 1 to 3 and 2 to 4. The CC subfamily has adjacent cysteines, whereas the CXC and CX3C subfamilies have one or three amino acids separating the first and second cysteines. The XC or C subfamily has a single cysteine at the amino terminus, whereas the first two cysteines are omitted in the XC subfamily. Chemokines can act on a variety of cell types via binding to multiple chemokine receptors.

Chemokine receptors are members of the seven transmembrane domain receptor families that signal via heterotrimeric G proteins (Figure 9). Humans have 22 chemokine receptors that can be divided into subfamilies that reflect the structural classification of the chemokine ligands. These include six CXC chemokine receptors (CXCR1 through CXCR6), 10 CC chemokine receptors (CCR1 through CCR10), one XC chemokine receptor (XCR1), and one CX3C chemokine receptor (CX3CR1). Binding of chemokine ligands are restricted to chemokine receptors within their subfamily. However, chemokines may bind multiple receptors within their chemokine receptor subfamily, which facilitates the recruitment of distinct populations of functionally related cells. For example, CXC chemokines primarily mediate the chemotaxis of polymorphonuclear neutrophils, whereas CC receptors primarily recruit subsets of T cells, eosinophils, basophils, dendritic cells, and monocytes. Binding of CX3CL1 to CX3CR1 recruits monocytes, immature dendritic cells and T-cell subsets, whereas binding of XCL1 or XCL2 to XCR1 mediates the recruitment of T cells and NKT cells.

TGF- β Family

The transforming growth factor- β (TGF- β) family of cytokines is comprised of 33 structurally related proteins in humans that

Figure 9 Chemokine signaling.

Figure 10 Transforming growth factor- β signaling.

regulate development, homeostasis, and disease. TGF- β is the prototypical member of this family and plays important roles in regulating cellular proliferation, differentiation, apoptosis, and adhesion. TGF- β also regulates cellular microenvironment and functions as a tumor suppressor. The TGF- β family can be divided into two branches. One branch is comprised of TGF- β isoforms (TGF- β 1, - β 2, and - β 3), activins (activin-A, activin-B, and activin-C), inhibin, lefty proteins, nodal, and myostatin. The other branch is comprised of bone morphogenetic proteins (BMPs), growth and differentiation factors (GDFs), and anti-muellerian hormone (AMH or MIS).

TGF- β is expressed as a precursor protein that contains a pro-peptide which is cleaved by furin-like proteases in the secretory pathway. The pro-peptide or latency-associated peptide (LAP) remains complexed with the mature peptide and functions as a chaperone during exocytosis, as well as facilitates the deposition of TGF- β in the extracellular matrix via an association with extracellular matrix proteins and TGF- β -binding proteins, which are large secreted proteins. The active TGF- β dimer signals via heterotetrameric receptors comprised of type I (also known as 'activin receptor-like kinases' or 'ALKs') and type II receptors that possess intrinsic serine/threonine kinase activity, as well as weaker tyrosine kinase activity (Figure 10). Binding of TGF- β stimulates the phosphorylation of the T β RI type I receptor by the T β RII type II receptor, which then signals via Smad transcription factors. TGF- β branch receptors signal via phosphorylation of Smads 2 and 3, while BMP branch receptors signal via phosphorylation of Smads 1, 5, and 8. Phosphorylation of two receptor-activated Smads (RSmads), such as Smad2 or Smad3, recruits a single common-mediator Smad, such as Smad4, to form a trimeric

complex that translocates to the nucleus and binds chromatin, as well as interacts with additional transcription factors, to regulate the transcription of target genes. TGF- β receptors can also activate non-Smad signaling pathways, such as MAP kinases, PI3K, and Rho-ROCK1.

BMPs play important roles in bone development, as well as bone remodeling and repair. This has led to the development of BMPs for the treatment of orthopedic surgery applications. Both recombinant human BMP-2 and BMP-7 have been approved by the US Food and Drug Administration for clinical use to repair bone injuries by promoting fracture healing or spinal fusion.

Cytokinesis

V Srivastava and D N Robinson, Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Abscission The final severing of the intercellular bridge, which is formed through ingression of the cleavage furrow.

Asters The radial array of microtubules originating from each spindle pole that extends toward the cell cortex.

Cell cortex The network of actin filaments and other proteins in close proximity to the cell membrane.

Central spindle The microtubule network extending between the two microtubule organizing centers of a dividing cell.

Cleavage furrow The region of cortex of a dividing cell where the cell constricts to form the intercellular bridge.

Contractile ring A dense array of actin and myosin II arranged in a ring-like structure in the cleavage furrow of many dividing cells.

Cortical tension The energy cost per unit increase in the cell surface area.

Cytokinesis The process of physical separation of a dividing cell into daughter cells.

Intercellular bridge The narrow, cylindrical connection between two daughter cells.

Laplace pressure The pressure generated at a curved fluid surface due to the surface tension of the fluid.

Midbody A compact protein-rich structure that contains a dense anti-parallel microtubule array, which is found in the intercellular bridge during late cytokinesis.

Cytokinesis

Subsequent to chromosome segregation during mitosis, the cell cytoplasm and other organelles are partitioned into two daughter cells through the process of cytokinesis. Correct cytokinesis is relevant for both normal development and disease. The uniform partitioning of cellular material is critical for normal cell proliferation, while asymmetric cell division is important in processes such as stem cell maintenance. In addition, cytokinesis defects have been implicated in many diseases, including cancer. Thus, detailed studies aimed at identifying the mechanisms that control cytokinesis are necessary to understand cellular behavior and for therapeutic applications.

In order to understand the mechanisms that regulate cytokinesis, it is essential to answer the following questions:

1. When and where does the division occur?
2. What are the factors responsible for this division?
3. How do those factors interact with each other to help the cell divide?

Like many biological processes, cytokinesis is a complex phenomenon involving a large number of players that interact with each other through multiple overlapping biochemical and mechanical pathways. Thus, cytokinesis is a great example of a biological control system, where the various feedback loops act in tandem to ensure the fidelity and robustness of cell division. Although the exact biochemical interactions are still unresolved to a large extent, a great deal is now known about the underlying mechanisms.

In spite of large cell-specific variations in the details of cytokinesis, there are certain universal characteristics of the process. Typically, cytokinesis proceeds through a series of stereotypical cell shape changes where the cell first rounds up, then elongates forming a cleavage furrow near the middle, whose constriction finally results in the separation of the daughter cells (Figure 1). These cell shape changes imply that cytokinesis is fundamentally

a mechanical process that requires major reorganization of the cytoskeleton and associated proteins to promote cellular contractility at the cleavage site. Hence, it is essential to supplement biochemical and genetic information with biophysical and mechanical studies to understand force generation, sensing, and transduction in a dividing cell.

Proteins That Regulate Cytokinesis

Methods

A variety of genetic, biochemical, and biophysical techniques have been used to identify and characterize cytokinesis genes. A traditional genetic approach involves phenotypic screening of mutant cell lines for cytokinesis defects, such as an increase in the number of bi- or multi-nucleated cells. Partial knockdown of protein expression using RNA interference (RNAi) has allowed functional analysis of essential genes, whose deletion can be lethal. By contrast, overexpression of genes has helped identify proteins that possess dominant-negative activities. Finally, live cell imaging of fluorescently labeled proteins gives information about their localization and dynamics *in vivo*. These techniques provide a powerful toolset for the functional analysis of protein dynamics, and have been combined with high-throughput methods for genome-wide screening to identify genes that regulate cytokinesis. In addition, directed screens and genetic suppression have helped map out biochemical pathways. However, to uncover entire pathways, these studies need to be supplemented with detailed characterization of protein interactions and *in vitro* biochemical reconstitution. Additionally, the use of pharmacological agents that modify the activity of specific proteins has allowed real-time phenotypic manipulation. This approach is especially useful for studying elements that are essential for cell survival or those that are required at multiple stages during the cell cycle. For example, cytokinesis defects were observed in post-mitotic cells treated with the microtubule-destabilizing compound, nocodazole. This established the involvement of

Figure 1 Stages of cytokinesis: a schematic diagram depicting the progression of cytokinesis in an amoeboid cell. Note that the contractile actomyosin network (CAN) is found throughout the cell cortex, but is enriched in the cleavage furrow.

microtubules in cytokinesis completion, apart from their role in chromosome segregation and cleavage site selection. Using a combination of various genetic and biochemical studies, a partial parts list of cytokinesis proteins has been compiled for many model organisms. Many of these are cytoskeleton-related proteins and kinases, while a large number of genes still remain uncharacterized.

Proteins

In most eukaryotic cell types, actin and the motor protein myosin II are known to form a contractile structure in the equatorial region of a dividing cell, whose ingression drives cytokinesis. Actin controls the cell mechanics by forming a highly dynamic network of semi-flexible filaments (Figure 2). During the myosin II power stroke, myosin pulls on the actin filaments as it releases the adenosine triphosphate (ATP) hydrolysis products, thereby generating mechanical force. Two myosin heavy chains combine with two essential and two regulatory light chains (ELC and RLC, respectively) to form a myosin II hexameric monomer, which then assembles into functional bipolar thick filaments (BTFs). Rho-kinase (ROCK) directs BTF assembly by activating myosin II through the phosphorylation of RLC. Additionally, heavy chain phosphorylation also controls BTF assembly and disassembly, both of which are required for normal cytokinesis. Although myosin II is the major mechanoenzyme during cytokinesis, it is not necessary for cytokinesis. Adherent cells can divide fairly normally in the absence of myosin II using traction forces to help with the initial cell elongation followed by cortical tension-driven furrow thinning. The effects of cortical tension, which serves to minimize the surface area-to-volume ratio, are highly reminiscent of the surface tension of a liquid droplet, which also helps drive droplet breakup.

In addition, several other actin-binding proteins, such as anillin and α -actinin in animals and cortexillin in *Dictyostelium*, help form a cross-linked actin network in the cell cortex (Figure 2), thereby regulating mechanical properties of the cortex. These proteins differ in their structure, actin-binding kinetics, force sensitivity, and cellular location. Collectively, these promote load-dependent force generation by myosin II and thereby cellular contractility. Some cross-linkers also contain lipid-binding domains (such as the pleckstrin-homology (PH) domain) that facilitate membrane attachment of the actin network. In animal cells, anillin is a potential scaffolding

Figure 2 A stylized diagram showing major components of the actin cytoskeleton in the cell cortex. Actin filaments form a dynamic highly cross-linked network that is connected through various actin cross-linking proteins. These proteins can regulate the tension in the network, thereby controlling the contractility of the cortex. The actin network is also attached to the cell membrane through some actin-binding proteins. The mechanoenzyme myosin II forms bipolar thick filaments and generates mechanical stress within the network by pulling on actin filaments.

protein that may provide membrane anchoring and link Rho, actin, and myosin II in the furrow. Rho is a major regulator of animal cytokinesis, as it controls both actin polymerization through formins and myosin II activation through ROCK. The levels of guanosine triphosphate (GTP)-bound active Rho in the cleavage furrow are controlled by the guanine-exchange factor (GEF) ECT2 and the GTPase-activating protein (GAP) MgcRacGAP.

Another major player in cytokinesis is the mitotic spindle, which helps define the axis of cell division and is involved in many signaling pathways. The spindle can deliver signals to the cell cortex that modulate cortical mechanics and direct cleavage-site selection and actomyosin contractile structure formation. This signal can either be in the form of a biochemical factor or be in the form of a purely mechanical cue like a change in

cortical tension or membrane potential. Many microtubule-based proteins such as the kinesin-6 family of proteins (mitotic kinesin-like protein-1 (MKLP-1)) are known to be important in cytokinesis and may localize differentially in a dividing cell. These proteins are believed to promote communication between the central spindle and the cell cortex.

Even though the membrane is thought to have a relatively limited contribution to the cellular mechanical properties, proteins involved in membrane dynamics, membrane fission and fusion, and vesicle transport are important in cytokinesis. The surface area of a dividing cell increases significantly as the furrow constricts. This requires the deposition of new membrane in the furrow region. In addition, constant membrane remodeling is required to relieve mechanical stress.

As the search for new genes that regulate cytokinesis continues, many nonprotein factors, including lipids and small metabolites, are also being examined for their role in cytokinesis. For example, the phosphoinositol-4,5-bisphosphate (PIP₂) is enriched in the cleavage furrow and can control the accumulation and retention of PIP₂-binding proteins during cytokinesis. In addition, many mechanical parameters, such as those described in the section Mechanics of cytokinesis, can affect the kinetics of cell division. To ensure robustness of cytokinesis, current models support the existence of multiple interacting, as well as parallel, mechanisms, thereby making the compilation of a comprehensive cytokinesis parts list challenging.

Spatiotemporal Events during Cytokinesis

Cytokinesis is tightly coupled to the cell cycle to ensure the proper segregation of genetic material into daughter cells. The onset of anaphase triggers major restructuring of the cytoskeleton, which initiates cytokinesis. No obvious factors for controlling the timing of cytokinesis initiation have been identified yet, but it is thought that some of the factors involved in the mitotic phase also regulate cytokinesis initiation. For example, Cdc2/Cdk1 inactivation during early anaphase or anaphase-promoting complex (APC)-dependent proteolysis could help initiate cytokinesis. The mitotic-exit network (MEN) and septation-initiation network (SIN) are other pathways that are known to regulate cytokinesis in some systems, and are relatively conserved across yeast, fungi, and plants.

Along with the temporal control of cytokinesis, the process is also regulated spatially. In most cells, cytokinesis occurs in the plane perpendicular to the cellular long axis generally close to the center of the cell. Thus, even from a purely geometrical perspective, the mitotic spindle is likely to be important in symmetry breaking and cleavage-site selection. Both the central spindle and astral microtubules are required for the correct positioning of the furrow, and likely deliver chemical signals to the cell cortex. The microtubule-dependent symmetry breaking can be achieved by the following mechanisms: motor-based transport of molecules, tracking of differential microtubule density in the cortex, or signals from the plus ends of microtubules themselves. Two classical models have been proposed to explain the role of spindle and the nature of these signals. The polar relaxation model proposes that signals inhibiting contractility are delivered to the polar cortex by the asters, while the equatorial simulation model argues for positive cues being delivered to the equatorial cortex by either the

central spindle or astral microtubules. Recent evidence suggests that both mechanisms most likely act synergistically to ensure fidelity of furrow initiation, though the exact signaling molecules involved remain unknown.

Once the cleavage furrow position is established, the actin cytoskeleton must reorganize to form the contractile actomyosin network. In animals, the activation of Rho GTP-binding proteins in the furrow region stimulates actin polymerization and myosin activation. For the enrichment of active Rho in the furrow, its diffusion must be restricted. One hypothesis argues for the role of anillin as a scaffold protein, as it can specifically bind to PIP₂ as well as activated Rho. Another theory supports microtubule-dependent accumulation of equatorial proteins.

The organization of actin and myosin II filaments varies with cell type. Actin and myosin II form a well-defined contractile ring-like structure (Figure 3(a)) in a number of cell types including the fission yeast *Schizosaccharomyces pombe*, while in many cells such as fibroblasts and *Dictyostelium*, actin forms a contractile meshwork (Figure 3(b)). The length and orientation of individual filaments are also cell-type dependent, ranging from ~1 µm long, roughly concentric filaments in *S. pombe*, to a more disorganized network of short ~100 nm actin filaments in *Dictyostelium*. Myosin II is a force-sensitive mechanoenzyme whose actin-binding lifetime and force generation depend on the tension in the actin filament. Thus, by forming junctions in the actin network and tethering it to the plasma membrane, actin cross-linkers help generate tension in the filaments, thereby increasing the overall myosin II-dependent contractility of the network, which drives constriction of the furrow cortex. The dynamic properties of these cross-linkers regulate the kinetics and mechanics of furrow ingression. Actin cross-linkers localizing in the cleavage furrow generally promote ingression, while other global cross-linkers inhibit contractility. After the initial accumulation, the furrow concentration of actin and myosin II remains largely unchanged as the furrow volume decreases, highlighting the importance of cytoskeletal disassembly during contraction. In summary, while actin and myosin II together form the active contractile force generation machinery responsible for furrow ingression, other actin-binding proteins act as regulators of cellular contractility by assisting or inhibiting cleavage furrow constriction.

As furrow ingression proceeds, a thin intercellular bridge is formed connecting the daughter cells. During later stages, the midzone microtubules, which are the microtubules between segregated chromosomes, condense to form a dense protein-rich structure called the 'midbody' within the bridge. The midbody is comprised of condensed anti-parallel microtubules and several other spindle-associated proteins such as the components of the chromosome passenger complex (CPC; including proteins such as Aurora B kinase and inner centromere protein (INCENP)) and the centralspindlin (MKLP1 and MgcRacGAP). A dividing cell can continue to exist at the bridge stage for long periods of time (from minutes to hours, depending on cell type) before the final separation, which may enable the cell to ensure proper segregation of cellular content.

Multiple models have been proposed to explain abscission, which is the final severing of the intercellular bridge. The final push of cytoplasm from the bridge may be a largely physical process driven by Laplace pressure that favors minimization of surface area to volume ratio. A second model

Figure 3 A comparison of actin cytoskeleton structure in cells forming a contractile ring (a) or a contractile meshwork (b). Note that the actin structures are shown to emphasize the cleavage furrow contractile organization, and the global actin network is not shown. The relative concentrations of actin, myosin II, and actin cross-linkers in the polar or equatorial cortex are also shown for both structures.

suggests that cell separation is promoted by the accumulation of secretory and endocytic vesicles adjacent to the midbody. Vesicle transport is also necessary to prevent membrane tearing as the furrow ingresses, increasing the total cellular surface area. A third model proposes that the invagination of the plasma membrane results first in hemifusion and finally cell cleavage. There is some evidence of differential membrane compositions in the equatorial versus polar cortices and in the inner versus outer membrane leaflet, which can activate signaling cascades and/or help in membrane fusion. Recently, the direct involvement of the endosomal sorting complex required for transport (ESCRT) in abscission has been shown using high-resolution imaging. However, similar to other steps

in cytokinesis, multiple mechanisms are likely to be working in parallel during abscission to ensure robustness.

Mechanics of Cytokinesis

Cytokinesis is a mechanical process during which a cell undergoes major mechanical deformation. Thus, an in-depth understanding of the effects of mechanical signals on cell mechanics and biochemistry is required. A diverse tool set is available to study cell mechanics during cytokinesis, allowing characterization of various mechanical parameters. While micropipette aspiration (MPA) studies are used to determine the elastic modulus and effective cortical tension, atomic force microscopy (AFM)

measures the bending modulus. The elastic modulus quantifies the deformability of the cell surface, and the cortical tension is a complex parameter that measures the energy cost per unit increase in cell surface area. The bending modulus reflects the stress required for bending a material. During cytokinesis, the initial deformation of a roughly spherical cell requires deviation from its quasi-steady state. This is resisted by the cortical surface tension, which favors a spherical cell. However, as the furrow continues to ingress, the curvature in the cleavage furrow changes so that the Laplace pressure eventually favors bridge thinning and abscission. Laser tracking microrheology (LTM) can be used to measure cortical viscoelasticity noninvasively. Viscoelasticity represents the time-dependent cellular response to stresses and affects the kinetics of furrow ingression by dampening the mechanical deformation, thereby allowing sufficient time for activation and stabilization of biochemical factors.

Treatment with actin depolymerizing drugs such as Latrunculin-A has established that the actin cytoskeleton is the main contributor of cell mechanics, though the cell membrane and microtubules also make some contribution. The actin cytoskeleton also undergoes remodeling with the application of internal or external mechanical stresses. The impact of mechanical stresses has been uncovered using micropipette aspiration, which allows the application of an external stress on the cell, similar in magnitude to stresses generated internally during cytokinesis. Many mechanosensitive proteins such as myosin II, which localize to the cleavage furrow cortex, also accumulate at sites where mechanical stress has been applied.

In contrast to the mechanical activation of biochemical reactions, the mechanical properties of the cell can be controlled biochemically. Knockdown of some actin cross-linkers softens the cell cortex significantly, leading to altered furrow ingression kinetics and a reduced ability to perform cytokinesis in suspension culture (where cell–substrate adhesion is absent). Interestingly, the overall deformability of the furrow is lower than the polar cortex, even though furrow undergoes major deformation during cytokinesis, which is attributed to a differential cortical distribution of mechanosensitive proteins during cytokinesis. This further illustrates the intricate interplay between biochemical and mechanical pathways during cytokinesis.

Species-Specific Cell Division Mechanisms

Though the essential sequence of events during cytokinesis is more or less conserved across organisms, there are significant differences in the mechanisms in various cell types. These become especially important in furrow positioning, where various organisms use diverse mechanisms to induce the initial symmetry breaking. Although actin and myosin II form the core contractile machinery in yeasts, protozoans, and animals, a similar system has not been found in plants. Cytokinesis in plants proceeds through a microtubule-dependent mechanism involving two additional microtubule structures, apart from the mitotic spindle, known as the ‘preprophase band (PPB)’ and ‘phragmoplast’. PPB is a ring-like microtubule and actin structure formed around the premitotic nucleus. During mitosis, actin dissociates from the PPB and the accumulation of a yet unknown factor marks the division site. The spindle then gives rise to the phragmoplast that expands toward the

cell cortex. Subsequent membrane trafficking and fusion at its edge leads to cell plate formation.

Similar to plants, the budding yeast cleavage site is determined early during mitosis by the accumulation of the small Rho GTP-binding protein Cdc42. Thus, the mitotic spindle is not crucial for budding site determination; rather the spindle aligns itself according to the polarization by Cdc42. By contrast, the cleavage furrow in fission yeast is determined by the position of the nucleus and the cylindrical geometry of the cell, as repositioning of the nucleus before early mitosis causes a shift in furrow location. Precursors of the contractile ring (or nodes) first appear near the center of the cell, which are attached to the membrane. These nodes then condense to form the contractile ring.

Cytokinesis in bacteria differs greatly from most eukaryotes as they do not contain organelles and the eukaryotic cytokinetic components. Rather, bacteria use an ancestral tubulin-related FtsZ cytoskeleton and have developed diverse intricate mechanisms for cytokinesis.

Conclusion

Cytokinesis is an essential biological process. Understanding the molecular mechanisms that regulate cytokinesis has great potential in the development of molecular targets against both cancer and infectious pathogens. It is an elegant biological control system comprised of multiple overlapping and parallel biochemical and mechanical pathways, promoting fidelity and robustness of cell division. Thus, along with the obvious therapeutic applications, cytokinesis studies are important for appreciating the complexity of biological shape morphogenesis.

Glossary

Cell cycle Sequence of events between mitotic divisions, divided into G1 (G standing for gap), S (synthesis phase), G2, and M (mitosis).

Cytokinin conjugate Compound formed by the union of a cytokinin and a sugar moiety.

Meristem Growing tip of roots and shoots.

Senescence Programmed aging leading to organ or plant death.

Two-component system Signal transduction system of bacteria, lower eukaryotes, and plants; involves autophosphorylation of a histidine kinase that transmits the signal via phosphorelay to response regulator proteins.

Cytokinins are plant-specific chemical messengers (hormones) that play a central role in the regulation of the plant cell cycle and numerous developmental processes. Cytokinins were discovered by F Skoog, C Miller, and co-workers during the 1950s as factors that promote cell division (cytokinesis). The first cytokinin discovered was an adenine (aminopurine) derivative named 'kinetin' (6-furfuryl-aminopurine), which was isolated as a DNA degradation product. The first common natural cytokinin identified was purified from immature maize kernels and named 'zeatin'. Several other cytokinins with related structures are known today. Cytokinins are present in all plant tissues. They are abundant in the root tip, shoot apex, and immature seeds. Their endogenous concentration is in the low nanomolar range. Typically, several types of cytokinins and their modified forms are present in a given tissue. Cytokinins can act over long distances or in the direct vicinity of the cytokinin-producing cells (paracrine signaling). Cytokinins may act also on the cell that produced them (autocrine signaling). Cytokinins are also produced by cyanobacteria, some plant pathogenic bacteria (e.g., *Agrobacterium tumefaciens*, *Pseudomonas savastanoi*, and *Rhodococcus fascians*), and the slime-mold *Dictyostelium discoideum*.

Cytokinin Structures

Naturally occurring cytokinins are adenine derivatives with a side chain at the N^6 -position (Figure 1). The structure and conformation of the N^6 -attached side chain can markedly influence the biological activity of the cytokinin. Depending on the structure of the N^6 -substituent, cytokinins are classified as isoprenoid or aromatic cytokinins. The biological activities of both classes are qualitatively similar but they may differ quantitatively in different processes. Isoprenoid cytokinins are the most abundant class. They are either isopentenyl (iP)-type cytokinins, having an isopentenyl N^6 -side chain, or zeatin-type cytokinins, having a hydroxylated isopentenyl N^6 -side chain. The side chain of a zeatin-type cytokinin occurs in either *cis* or *trans* configuration, depending on which of the two methyl groups is hydroxylated. The *cis* form is usually much less active. Reduction of the double bond in the side

chain leads to dihydrozeatin. Aromatic cytokinins have an aromatic benzyl group at N^6 . They occur more rarely and much less is known about them. Because of their greater stability, aromatic cytokinins are often used in tissue culture; an example is benzyladenine. In addition, there are the structurally unrelated phenylurea-type cytokinins (e.g., diphenylurea and thidiazuron), a class of synthetic cytokinins. These cytokinins are highly active but do not occur naturally.

Cytokinin Biosynthesis and Metabolism

The rate of *de novo* synthesis, metabolic interconversion, and breakdown are, together with transport processes, relevant to the regulation of cytokinin homeostasis in cells. Cytokinin metabolism includes mainly conversions among cytokinin bases, ribosides, ribotides, side-chain modification, conjugation and conjugate-hydrolyzing reactions, and cytokinin degradation.

Biosynthesis

The initial and rate-limiting step of biosynthesis of isoprenoid-type cytokinins is the transfer of the isopentenyl moiety from dimethylallyl pyrophosphate (DMAPP) to adenosine monophosphate (AMP), adenosine diphosphate (ADP), or adenosine triphosphate (ATP). The reaction is catalyzed by DMAPP::AMP/ADP/ATP isopentenyltransferases (IPT). ADP and ATP are the preferred substrates of most of the known plant IPT enzymes, while bacterial enzymes prefer AMP. The reaction leads to the formation of isopentenyl-AMP, -ADP, and -ATP, which are the precursor molecules of biologically active cytokinins. The isopentenyl side chain is subsequently hydroxylated to form zeatin-type cytokinins (Figure 1). An alternative pathway, in which an already hydroxylated side chain is directly added to the N^6 -position of the adenine moiety, may exist. IPT enzymes are encoded in *Arabidopsis* by a small gene family with seven members (*AtIPT1*, *AtIPT3*–*AtIPT8*). *AtIPT* genes are expressed in specific tissues of the root and shoot (e.g., vasculature), indicating that cytokinin synthesis occurs in all major organs. Another possible source of cytokinins is

Figure 1 Chemical structures of some naturally occurring and synthetic cytokinins. Common names and abbreviations are indicated below the structures. The numbering of purine ring atoms is shown for kinetin.

transfer RNA (tRNA), since tRNAs of most organisms contain isopentenylated adenine and other structural derivatives with cytokinin activity. However, it is generally assumed that tRNAs play only a minor role, if any, as a cytokinin source.

Interconversion

A characteristic feature of cytokinin metabolism is the rapid metabolic interconversion of base, ribosides, and ribotides. The biologically most active form of cytokinins is the base. Attachment of ribose or ribose-5'-phosphate to the N⁹ atom of the adenine ring leads to the formation of ribosides and ribotides, respectively, which do have lower activities (**Figure 1**). Interconversion of cytokinins is presumably an important mechanism to regulate the concentration of active compounds. Cytokinin ribosides are probably relevant as a transport form. The interconversions may be catalyzed by the same enzymes that metabolize adenine, adenosine, and AMP. The conversion

between the *cis*- and *trans*-isomers of zeatin is catalyzed by the enzyme *cis-trans* zeatin isomerase. Zeatin is converted to dihydrozeatin by a nicotinamide adenine dinucleotide phosphate (reduced)-dependent zeatin reductase.

Conjugation

Cytokinins can be stably or transiently inactivated by glycosylation of the purine ring or of the side chain. The purine ring can be glycosylated at the N³-, N⁷-, and N⁹-positions. In addition, the N⁶-side chain group can form O-glycosyl conjugates if it bears a hydroxyl-group. Most often, glucose is the conjugated sugar molecule, more rarely xylose is attached. N⁷- and N⁹-conjugates are biologically inactive and extremely stable. Thus, they are irreversibly inactivated cytokinins. N³- and O-conjugates are biologically inactive but can be readily hydrolyzed. They are believed to be transient storage forms of cytokinins. Glycosyl conjugation is considered to be important in

the regulation of cytokinin activity levels, at least in some tissues and species. Several genes coding for cytokinin glycosyltransferases and glycosidases have been identified. Some conjugates of cytokinins and amino acids (alanine) have been described as well.

Catabolism

Cytokinins are irreversibly degraded in a single enzymatic step by oxidative cleavage of the N^6 -side chain. The reaction is catalyzed by cytokinin oxidases/dehydrogenases (CKX), which contain flavin adenine dinucleotide as a cofactor. The reaction products are adenine and an aldehyde. The preferred substrates of CKX are isopentenyladenine, zeatin, and their corresponding ribosides. Ribotides, *O*-glucosides, dihydrozeatin, and aromatic cytokinins are not degraded by CKX. The *Arabidopsis* genome contains seven *AtCKX* genes, which are preferentially expressed in zones of active cell division and growth. The corresponding enzymes are located in the endoplasmatic reticulum, in the apoplast, and in the vacuole.

Cytokinin Transport

Cytokinins are transported from roots to shoots in the xylem, and in the opposite direction in the phloem. Transported cytokinins may have a role in coordinating root and shoot development, for example, by carrying information about nutrient availability. Multiple cellular importers and exporters are required to allow efficient mobilization and targeted translocation of cytokinins, but very little is known about cytokinin transporters. Transport studies indicate that a common H^+ -coupled high-affinity purine transport system transports cytokinins.

Cytokinin Signaling

The mechanism of cytokinin signaling is just beginning to emerge. The cytokinin signal is perceived and transduced by a multistep phosphorelay system through a complex form of the two-component system (TCS) pathway. The TCS is common among prokaryotes and lower eukaryotes; among the higher eukaryotes, it is unique to plants. In this signaling system, a membrane-located receptor kinase with an extracellular ligand-recognition domain (sensor) dimerizes upon binding a ligand and autophosphorylates a histidine within its cytoplasmic transmitter domain. The phosphoryl group is first transferred to an aspartate residue within the receiver domain at the C terminus of the receptor and from there to a His-containing phosphotransmitter (Hpt), which ultimately phosphorylates and thus activates a response regulator (RR) at a central Asp residue (see [Figure 2](#)).

Signal Perception

Cytokinin receptors are histidine kinases consisting of an extracellular sensing domain, a cytoplasmic histidine kinase transmitter, and receiver domains. Three cytokinin receptors (CRE1/WOL/AHK4, AHK2, and AHK3) have been identified in *Arabidopsis*. They all share a ~270-amino-acid long extracellular

cyclases/histidine kinases associated sensing extracellular domain, which presumably recognizes cytokinin. This domain might have been acquired by plants through lateral gene transfer from cyanobacteria. Loss-of-function mutants of CRE1/WOL/AHK4 lack the phloem in their primary roots, indicating a role for cytokinins in embryo development.

Signal Transduction

Current knowledge suggests that downstream signaling components of the cytokinin signal-transduction pathway in *Arabidopsis* consist of five Hpt and 22 RRs of the A- or B-type. Hpts transmit the signal from the receptor, which is presumably localized in the plasma membrane, to B-type RRs, which are in the nucleus. B-type RRs consist of an N-terminal receiver domain and a C-terminal output domain, containing a DNA-recognition motif called genomic and RNA profiling (GARP), which is distantly related to the Myb repeat. The DNA motif optimal for binding is 5'-(A/G)GAT(T/C)-3'. Activated B-type ARRs transcribe primary response genes of cytokinins. Some of the known primary response genes, which are rapidly and specifically upregulated by cytokinins, code for type A RRs. Type A RRs resemble type B RRs but lack the C-terminal DNA binding and activation domain. Type A RRs fulfill at least two different functions. On the one hand, they exert a negative feedback regulation of the cytokinin signaling pathway through protein-protein interaction. On the other hand, they mediate the cytokinin-dependent modulation of other pathways, for example, light signaling. A-type RRs can be positive or negative regulators, depending on the individual RR and the output reaction analyzed.

Cytokinin Functions

Cell Cycle

Cytokinins are required for cell division during embryogenesis in the shoot apical meristem, young leaves, the cambium, and cultured plant cells. By contrast, they have a negative regulatory role in the root meristem. Cytokinin controls the exit of dividing cells from this meristem. Changes in cytokinin levels occur during the cell cycle of cultured cells, the level being highest during the late S and before the M phase. Cytokinins have been functionally linked to all stages of the cell cycle but their mechanism of action has only been partially elucidated. Cytokinin upregulates expression of the D-type cyclin gene *CycD3*, which is important in regulating the G1/S-transition of the cell cycle. Cytokinin increases the number of replication origins during S-phase and it may also play a role in regulating G2/M transition.

Plant Development and Growth

Cytokinin participates in regulating numerous aspects of plant development throughout the life cycle. These include seed germination, cotyledon expansion, chloroplast differentiation, de-etiolation, differentiation of vascular tissue, apical dominance (shoot branching), root elongation and branching, nutritional signaling, regulation of sink strength, the transition from the vegetative to the reproductive growth phase, flower

Figure 2 A model for cytokinin signal transduction via a His-to-Asp phosphorelay. The structure of CRE1/WOL/AHK4 is shown as an example. Ligand binding induces receptor dimerization and autophosphorylation. Transfer of the phosphoryl group by activated receptors activates histidine phosphotransmitter proteins (Hpts), which transport the signal from the cytoplasm to B-type RRs in the nucleus. B-Type RRs transcribe target genes, among them A-type *ARR* genes. A-Type RRs may downregulate the primary cytokinin signal response via a negative feedback loop, modulate downstream activities of cytokinins in a positive or negative fashion, or modulate other signaling pathways through protein–protein interaction. A more complex regulation than shown in the model may exist. D, aspartate residue; H, histidine residue; P, phosphoryl group.

and fruit development, leaf senescence, and plant–pathogen interactions. A role for the hormone in vascular morphogenesis during embryonic development is firmly established. During postembryonic development, cytokinins are required to maintain meristem activity and leaf development in the plant shoot. Local exogenous cytokinin application to the shoot leads to premature growth of lateral buds, retarded leaf senescence, partial photomorphogenesis in the dark, increased sink strength, and an altered vasculature. In contrast to their stimulatory activities in the shoot, cytokinins have a negative regulatory role in the control of root elongation and branching. Additionally, cytokinin regulates important physiological

parameters that determine biomass formation and distribution via central genes of primary metabolite pathways, including invertases, hexose transporters, and key genes of phosphate and nitrogen metabolism and signaling (e.g., nitrate reductase). Changes in cytokinin levels are generally positively correlated with levels of mineral nutrients, especially nitrogenous nutrients. Cytokinin levels are decreased by water stress. *In vitro*, the ratio of cytokinin to auxin determines the differentiation of cultured plant tissues to either shoots or roots. A high cytokinin to auxin ratio promotes shoot formation; a low ratio promotes root formation. Owing to their stimulatory effect on plant regeneration, cytokinins are widely used in plant tissue culture.

Pathogenicity

Cytokinins are produced by several plant pathogenic bacteria and play a role in pathogenicity. One such pathogen is *A. tumefaciens*, the causative agent of the crown gall disease. During the infection process, *A. tumefaciens* transfers a small stretch of DNA, the T-DNA, to the host plant, where it becomes integrated in the nuclear genome. The T-DNA harbors an *IPT* gene, which is expressed in the host cell and causes cytokinin overproduction. This leads, together with an enhanced auxin content, to tumorous cell proliferation. Other cytokinin-synthesizing pathogens are *Pseudomonas syringae*, which induces gall formation and *R. fascians*, which causes fascinations and a growth abnormality called 'witch's broom disease'. The root-nodule forming and nitrogen-fixing plant symbiont *Rhizobium* sp. is also known to produce cytokinin.

Biotechnology

Practical use of cytokinin in agriculture is currently limited. Modulation of the endogenous cytokinin content of plants or interfering with cytokinin signaling has a high potential for biotechnological applications in agriculture. Plants with increased cytokinin content are more branched and senesce later. Moreover, cytokinins alter sink-source relations, a promising approach to improve yield attributes. Plants with reduced cytokinin content develop a larger root system. An improved root system means improved acquisition of

minerals and water, factors which are often limiting for plant growth.

Cytoskeletal Motors: General Principles

R S Rock, The University of Chicago, Chicago, IL, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Actin-binding protein (ABP) A protein that binds to actin and modulates its function. Functions of ABPs include nucleating new filaments, decorating the sides of filaments, bundling filaments, and severing filaments.

Gating A mode of regulation where biochemical or mechanical events on one catalytic domain of a motor cannot proceed until separate events that serve as checkpoints are completed on the other

catalytic domain; this is related to half of the sites reactivity.

Half of the sites reactivity A form of allostery where one out of two catalytic sites in a protein is inactive at any given time. Thus, the protein has half as many active sites as expected.

Microtubule-associated protein (MAP) A protein that binds to microtubules and modulates their function. Functionally similar to the ABPs.

A Walking Model for Cytoskeletal Motors

In the following narrative, we describe the structure of the cytoskeletal motors and the arrangement of their filament tracks. For simplicity, we consider these motors to be bipedal molecules, walking along their filament tracks much like we walk on the ground (Figure 1). In this analogy, the two feet are the two motor domains that bind to the track and turnover adenosine triphosphate (ATP) as fuel. The feet bind stereospecifically to the track, always facing the same end of the cytoskeletal filament. This feature allows motors to travel in one direction, set by the polarity of the track. The two legs are elongated structural elements that swing from one orientation to another. These legs vary considerably in length, flexibility, and structure between and within motor families. Finally, the hips define the point where the two legs join and where cargo or scaffolding proteins are attached. In describing the parts of cytoskeletal motors in this way, we are dispensing with the historical but confusing description of heads, necks, and tails. These motors take forward steps by picking up their trailing foot and placing it in the leading position, yielding a rapid and discrete step. The fuel for this process is ATP. Many motors are processive, meaning they move continuously and take many steps before detaching from their tracks. Those that are non-processive are specialized and usually operate in large arrays to support continuous movement.

Following the motions of these intricate machines required the development of fundamentally new biochemical and biophysical approaches. The key challenge was the difficulty in monitoring the main product of motor proteins, namely motion. One cannot simply mix motors, tracks, and ATP in a tube and measure total motion; one must track objects as they move. Furthermore, multiple motors would compete with each other unless the system was properly engineered. The Spudich group developed the first successful *in vitro* motility assays in the 1980s. Their gliding filament assay monitored the movement of labeled actin filaments over a surface coated with many myosin motors. This system was later adapted to track the motion of microtubules driven by kinesin or dynein. Further refinements led to single-molecule motility assays that allowed us to follow the action of individual motors, and to

avoid complications associated with tracking many unsynchronized motors at once.

These single-molecule assays now allow us to track the individual parts within the motor protein. For example, fluorescent probes placed on the hips will report the location of the center of mass of the motor protein as it steps along its track. Modern techniques allow us to track the location of this fluorescent probe to within a few nanometers. If a probe is instead placed on the leg near the foot, a specific long-short-long-short stepping pattern is seen. To see why this pattern emerges, imagine tracking the location of your right knee as you walk. With your right foot in front as you take a step with your left foot, your right ankle will rotate, with a small translation of your right knee forward. With your next step, you pick up your trailing right foot and swing it forward, resulting in a large translation of your right knee. Thus, by careful placement of probes, it is possible to map out the moving parts of the cytoskeletal motors. These observations largely confirm many aspects of the walking model for each of the three cytoskeletal motors. In a stunning recent development, the Ando group imaged myosin motors walking along actin filaments in solution with a video-rate atomic force microscope. In this experiment, the legs of a myosin motor are clearly resolved, allowing us to see the walking pattern of a motor protein in real time, and without the need to attach molecular probes to the motor.

Caveats of the Walking Model

Of course, the walking model described above is an oversimplification, and it is easy to stretch the analogy too far. The analogies extracted from walking around the macroscopic world is of little help when considering the motion of cytoskeletal motors as they are continuously buffeted by thermal forces from the solution. Here, we describe some of the features of cytoskeletal motors that diverge from our expectations derived from the motion of our legs as we walk.

The first major difference is in where the driving force is generated. When we walk, we are primarily using the large muscle groups found in our hips and thighs. For kinesins and myosins, however, the motor domain is found in the feet, where it drives the rotation of the ankle. The notable exception

Figure 1 A general stepping scheme for cytoskeletal motors. A generic motor is shown, with motor domain feet (red), elongated legs that transmit motions (blue lines), and hips where the two legs join and cargo is attached (black circle). These motors walk along lattice sites on a cytoskeletal filament (black line with open black circles). The legs either may be rigid, as shown or may be flexible and buttressed against the feet, as is the case for kinesin. Dynein places the motor domain in the hips instead of the feet. The two phases of a step are shown. In phase 1, the leg swings, placing the free foot closer to its next lattice site on the filament. In phase 2, the free foot diffuses around the location of the hips, until it rebinds the filament. Phases 3 and 4 repeat the processes in 1 and 2, illustrating the transition to the next step.

is dynein, which, like us, seems to drive motility from the hips where its ATPase with associated activity (AAA) domains do the work. But without movement at the hips, how do these two cytoskeletal motors walk? We would certainly fall over with motion only at the ankles.

Here is where the massive thermal forces in the microscopic environment take over. At the instant the back foot releases from the track, the ankle of the front foot swings (an event sometimes called the ‘powerstroke’ or ‘working stroke’ of the motor). The free foot now undergoes a diffusive search for a new binding site on its track (Figure 1). Thus, the pivoting at the hips is entirely driven by Brownian motion of the free leg. This search is centered upon the location of the hips, and because the hips move forward when the bound leg swings forward, the search is biased toward forward sites on the track.

A second major difference has to do with the structure of the track. Actin filaments and microtubules both present a fixed lattice of binding sites where the feet may step. This feature places significant constraints on the stepping pattern of motor proteins. Whereas we can change our stride when walking along the ground, motor proteins are stepping on discrete sites, much like stepping stones in a river. Depending on the spacing of these stones, they have either many options (like myosin VI stepping along actin or dynein along microtubules) or few (like kinesin along microtubules, where only a single tubulin binding-site is available and stepsizes are therefore highly regular).

We might expect that the motor proteins have evolved to precisely match their tracks, much like the gears meshing in a Swiss watch. However, this level of precision does not seem to be the case for cytoskeletal motors. For example, a single leg of myosin V will naturally swing 25 nm with each step. However, the next binding site along actin is 36 nm away. The myosin V must rely on thermal forces to carry it the rest of the way. When the free foot lands on actin, the whole myosin must distort to make up the 11-nm distance. It is as if it must stretch to reach a stepping stone that is just a bit farther than its natural stride. This stretching is one way for a cytoskeletal motor to keep track of which foot is in front, and which foot is in back. A foot that senses a rearward tug is in front, and is in back if it senses a forward tug.

A third difference with our walking experience has to do with the timing of events in stepping. We walk in a rather rhythmic fashion, with our feet touching the ground after a nearly constant time in the air. However, cytoskeletal motor steps are coordinated through discrete biochemical events, and the timing of these events is stochastic.

Finally, our discussion of walking motors leaves out an entire class of motors that do not walk with two feet at all. There are certain cytoskeletal motors that may act more as tethers or crosslinkers, and can operate with only a single foot. There are others that have feet that spend most of their time detached from the track, up in the air, as it were. These motors will typically operate as part of a large ensemble, which virtually guarantees that at least one foot will be on the track at all times. Rather than being bipedal motor proteins, these motors (like skeletal muscle myosin) bear closer resemblance to centipedes with many legs, but with only a few feet on the ground at any given time.

Regulation of Stepping

Our legs are under conscious control; we decide when and where we want to move them. Clearly, molecular motors are not able to make the same decisions. Nevertheless, motors must be regulated in some manner; otherwise, they would make serious errors such as moving to their final destination before their cargo is attached. We have now uncovered a number of these forms of regulation.

The most direct forms of regulation are modifications of the motor or the track. A number of motors switch activity based on posttranslational modifications. For example, certain myosins are phosphorylated, either directly or on their associated light chains, which controls their ability to engage their actin

track or to assemble into larger structures. Certain kinesins are likewise regulated by phosphorylation. Track-based modifications may take a number of forms. Accessory proteins (ABPs for actin, MAPs for microtubules) or posttranslational modifications (acetylation of microtubules) can recruit or inhibit certain motors. Moreover, certain architectures of cytoskeletal filaments may be required for motor activity. Some kinesins are found at overlapping, antiparallel microtubules found at the central spindle, while some myosins select bundled actin filaments in preference to single actin filaments.

An emerging regulatory theme is the idea of cargo activation of cytoskeletal motors, which ensures that motors do not engage their tracks and start moving prematurely. Cargo binding activates the motor in a concerted manner, removing the requirement for separate modes of regulation for cargo binding and motor activation. There are a couple of common forms of cargo activation. In one, the motor protein will fold back on itself in the absence of cargo. This folded configuration, where the motor is grabbing its own feet, is autoinhibited and incapable of walking along the track. Cargo binding releases this folded configuration, and simultaneously activates the motor and allows it to commence walking. A related form of regulation occurs when cargo binding triggers motor dimerization. In the absence of cargo, certain motors (e.g., the kinesin KIF1a or myosin VI) are monomeric in solution, as if they have only one foot and leg. Individual monomeric motors can bind to cargoes to trigger motor dimerization and activation. Thus, it is not easy to predict the arrangement of feet and legs for a motor protein without considerable structural work on the cargo-binding domains and associated scaffold proteins.

A cautionary tale is warranted here. In recent years, a number of groups have claimed that certain molecular motors must operate as monomers within the cell, since full-length versions of the motors are monomeric in biochemical assays. These groups have bolstered these claims by expressing isolated dimerization domains from these motors and showing that they do not dimerize in their hands. However, these claims neglect the influence of the cargo-binding domains of the motors. If cargo binding is tight and leads to motor dimerization at the point of the cargo-binding domains, then the local concentration of the two motor domains can exceed one millimolar based on the volume defined by the dimensions of typical motor proteins. Therefore, extremely weak dimerization that is difficult to detect may still be critical for motor function. Indeed, motors that form regulated dimers likely require weak dimerization domains, so that dimers form only after the assistance of cargo and not spontaneously.

Coordination and Gating

We walk in a highly coordinated manner. A set of sophisticated neural circuits triggers muscle contraction in the correct sequence, so that our back leg lifts and our front leg swings. Proper coordination involves proprioceptive neurons that sense the orientation of our limbs. Likewise, cytoskeletal motors often employ forms of coordination to ensure that the back leg lifts before the forward leg, and also to ensure that both legs do not lift at the same time.

For cytoskeletal motors, such coordination is achieved through carefully tuned ATPase kinetics. In particular, these motors switch off the ATPase activity of one of the two feet.

This alternating inactivation is commonly called 'half of the sites reactivity' or 'gating'. It is thought that an allosteric, strain-sensitive mechanism is responsible for identifying front foot, rear foot, and switching of ATPase activity from one foot to the other, but the molecular details remain obscure.

There are two general ways for a motor to be gated. In one mechanism, the progress of the front foot is halted. The front foot knows that it is the front foot when its leg is leaning backward. In this mechanism, this front foot waits until the back foot releases. At this moment, the motor is vulnerable to detach from the track. To avoid this premature detachment, the kinetic pathway requires a slow event in the bound front foot, which occurs sometime after its leg swings forward. This slow event allows plenty of time for the free foot to rebind to the track before the bound foot releases. Thus, a kinetic competition exists between taking another forward step and detaching from the track, and the kinetics favor the landing of the free foot.

In the second mechanism, the action occurs on the back foot. A slow back foot waits for a tug from the front foot before continuing through its ATPase cycle and detaching. Although the essential features are similar to front-foot gating, a curious feature of this mechanism is that the allosteric communication mechanism does not actually increase the processivity of the motor. The strain that accelerates stepping is only felt once both feet are on the track and motor is no longer vulnerable to detach. Instead, strain is used here to increase the stepping speed. In practice, mixed models are possible, where gating occurs on both the front foot and the back foot at the same time.

Finally, some motors manage to walk processively even without gating or half of the sites reactivity. They do so with sticky feet that remain bound to the track nearly all of the time. Since the two feet step independently of each other, these motors make many mistakes, lifting the front foot before the back. The stepping pattern of these ungated motors resembles a biased diffusive walk rather than the regular forward stepping that we would expect. The common structural feature of these ungated motors is that they have long and flexible legs that do a poor job of transmitting strain. However, even these flexible motors must be gated some fraction of the time. If the two feet have taken diffusive steps and end up far apart on the track, all of the slack in the flexible legs may be absorbed. In this case, the feet are no longer independent: the motor would have no choice but to lift its back foot with the next step.

Mechanical Performance

All cytoskeletal motor proteins pull on filaments, generating force. Moreover, all motor proteins have fundamental limits on their ability to perform mechanical work. These limits are important to consider in the cellular context, where drag forces experienced by the cargoes or resisting tension in cytoskeletal filaments may become significant. In general, if an external force that opposes forward motion is applied to a motor protein, its forward stepping rate will decrease. Eventually, the forward stepping rate decreases to the point where it equals the backward stepping rate. At this force, the motor is stalled, meaning that it can move no farther, on average.

Rate-constants for biochemical events coupled to displacements, such as working strokes in cytoskeletal motors, depend

Figure 2 Overall stepping rates as a function of load. The general case is shown, with a load-dependent event and a load-independent event occurring in series with each mechanical step. The solid line is for $k_i = 10 \text{ s}^{-1}$, $k_0 = 200 \text{ s}^{-1}$, and $d = 5$. Note that the stepping rate does not vary with force around zero force, as k_i dominates. The dashed line uses the same parameters, except $k_i = 1000 \text{ s}^{-1}$. Here, the stepping rate does vary with force near zero force, as k_0 dominates in this region.

on the external force with a Boltzmann-like dependence, first described by Bell in 1978:

$$k(F) = k_0 e^{-Fd/k_b T}$$

Here, k_0 is the rate constant at zero force, F is the applied force, d is the distance to the transition state, and $k_b T$ is thermal energy ($\sim 4 \text{ pN nm}$ at room temperature). The sign convention here has positive forces (load) opposing the transition, so that the exponential factor is less than one and the rate constant is reduced with increasing force. The remarkable feature of Bell's equation is that it allows us to measure distances associated with a structural change solely through the effect on rate constants. Note that the distance, d , is the distance to the transition state, not the step size of the motor. Large values of d correspond to highly force-sensitive transitions, while low to zero values of d are transitions insensitive to force. For a unidirectional swing of the leg, we expect that d will be less than the motor step size.

Practical measurement of d requires instrumentation that can measure stepping rates as a function of applied force. Optical traps are ideal instruments to apply precise forces to cytoskeletal motors as they step. Because each step may require force-sensitive and force-insensitive events that occur in series, the general expression for the observed stepping rate is

$$k(F) = \frac{k_i k_0 e^{-Fd/k_b T}}{k_i + k_0 e^{-Fd/k_b T}}$$

where k_i is a composite rate for all force-insensitive transitions. The composite force-dependent rate, k_0 , could be separated into multiple individual force-dependent transitions, each with their own d , but it is rarely the case that the additional parameters are justified by the data. The most common scenario for cytoskeletal motors is a rate-limiting and load-independent transition described by k_i . The signature of this mechanism is load-independent stepping at low load, followed by a transition to load-dependent stepping over a narrow range of forces as k_0 eventually dominates (Figure 2, solid line). Alternatively, k_0 may itself be rate limiting, which requires load-dependent stepping near zero load (Figure 2, dashed line).

The manner in which a cytoskeletal motor approaches stall can significantly constrain its role in the cell. There are three general ways that a cytoskeletal motor can approach stall: (1) it can detach before reaching stall, (2) it can stop stepping altogether as it approaches the stall force (static stall), or (3) it can step forward and backward around the stall force (dynamic stall). To transport cargo, any of the three options are acceptable since the motor has an opportunity to reengage a track after a failed run. However, to regulate the tension of cytoskeletal filaments, the best option is (3), dynamic stall. As the motor experiences superstall loads, it can relax to the original stall force without detaching and suddenly dissipating tension. In contrast, a static stall motor acts more like a ratchet, reeling in slack filaments but stubbornly holding on as load increases. Likewise, detaching before the stall force is reached is a poor option for a cytoskeletal motor that regulates tension, since the detachment force will vary considerably with each run.

Conclusion

The biped walking picture of cytoskeletal motors is a useful starting framework for understanding how they operate within the cell, especially in understanding the order of the mechanical events. However, we must remain aware that there are important differences in the mechanical environment and the coordination mechanisms that affect how motors walk relative to how we walk.

Glossary

Cadherins Single-pass transmembrane proteins that mediate calcium-dependent cell–cell adhesion.

Epithelia Sheets of tightly packed cells that cover a body surface or line organs and body cavities.

Extracellular matrix An organized network of proteins and polysaccharides that fills the extracellular space of tissues and is produced by the surrounding cells.

Integrins Transmembrane linker proteins that are receptors for extracellular matrix proteins and link the extracellular matrix to components of the cytoskeleton.

Intermediate filaments Cytoskeletal filaments, typically 10 nm in diameter, found in higher eukaryotic cells.

Signal transduction The propagation of a chemical or mechanical stimulus to affect a cellular response.

The Desmosome

Desmosomes are prominent in tissues that are subjected to mechanical stress. Found most abundantly in stratified squamous and simple epithelial tissues, desmosomes have also been noted in the myocardium, brain meninges, and follicular dendritic cells of the lymph nodes. These specialized anchoring junctions function to mediate intercellular adhesion and maintain tissue integrity by connecting sites of cell–cell contact to the highly tensile intermediate filament (IF) cytoskeleton. In the myocardium, desmosomes have classically been described as part of a junctional complex called the intercalated disk, also containing adherens junctions and gap junctions, which chemically and electrically couples beating cardiac myocytes. More recently, it has been appreciated that in mammals a mixed type of cell–cell junction termed the ‘area composita’, consisting of desmosomal and adherens junction components, is formed postnatally. The functional significance of this junction or its species specificity is not understood.

Desmosome Ultrastructure

Ultrastructurally, the desmosome appears as a mirror image of a highly organized, electron-dense region adjacent to the cell membrane (Figure 1, left). The plasma membranes of adjacent cells are separated by a ~30-nm space containing an electron-dense

midline, likely composed of the extracellular domains of the transmembrane desmosomal components. Just internal to the plasma membrane is an electron-dense outer plaque containing the intracellular desmosomal components. Interior to this region is a less-dense, IF-rich fibrillar inner plaque.

Structure and Molecular Components of the Desmosome

The basic blueprint of a desmosome comprises molecular components that fall into three main gene families: desmosomal cadherins, armadillo family members (plakoglobin (Pg) and plakophilins (PKPs)), and plakins. Several studies suggest that these molecules are arranged linearly in this order from the cell-surface inward and function together to indirectly tether the IF cytoskeleton to the cell membrane. This structural feature is shared by the closely related actin cytoskeleton-tethering adherens junctions, which have a similar molecular blueprint (with classical cadherins, armadillo proteins (β -catenin and p120), and α -catenin in place of their desmosomal counterparts). Lateral clustering of these proteins enhances the strength of the junction. Nonadhesive functions have also been proposed for several of these molecules. The best-characterized desmosomal components (Figure 1, right) are discussed in detail below. However, minor components, including pinin, perp, corneodesmosin, and desmocalmin/keratocalmin, have also been described and may have tissue- or differentiation-specific functions.

Figure 1 Molecular composition and structure of the desmosome. (Left) Desmosome ultrastructure is shown in this electron micrograph of bovine tongue epidermis. (Right) Desmosomal proteins, their interactions, and their approximate position within the organelle are depicted in this schematic diagram of the desmosome. Reproduced from Kowalczyk AP, Bornslaeger EA, Borgwardt JE, et al. (1994) Structure and function of desmosomal transmembrane core and plaque molecules. *Biophysical Chemistry* 50: 97–112.

Desmosomal cadherins

Two types of glycosylated, type I transmembrane adhesive cadherin proteins are found in the desmosome, desmogleins (Dsgs) and desmocollins (Dscs). Different genes encode four isoforms (1–4) of desmogleins and three isoforms (1–3) of desmocollins, which are expressed differentially in various cell types and in a differentiation-specific manner in complex stratified epithelia. The Dsc isoforms are further subdivided into two types, a longer a form and a shorter b form. Like classical cadherins, both Dsgs and Dscs have a highly conserved calcium-binding extracellular domain, membrane spanning region, and catenin-binding intracellular cadherin segment (ICS) (not present in Dsc b), while Dsgs contain additional, unique cytoplasmic subdomains. Emerging evidence implicates these unique subdomains of Dsg1 in epidermal differentiation through regulation of epidermal growth factor receptor (EGFR)–extracellular-signal-regulated kinase (Erk) signaling axis. Since most of the structural variability between Dsg family members rests in this unique region, it is possible that individual family members regulate distinct signaling pathways. Dsgs and Dscs are thought to function primarily in mediating homo- and/or heterophilic calcium-dependent adhesion across the membranes of adjacent cells. Severe blistering of the skin or lesions on the hands and feet are consequences of genetic, autoimmune, and bacterial diseases that compromise the adhesive function of these molecules (Table 1).

Armadillo family members

Proteins with homology to the *Drosophila* segment polarity protein, armadillo, are important structural components of the desmosome, linking the desmosomal cadherins at the plasma membrane with intracellular cytoskeleton components. These proteins contain a 42-amino-acid repeated motif called the arm repeat, which is thought to mediate protein–

protein interactions. Pg is one arm protein whose presence in both adherens junctions and desmosomes is selectively regulated. In the desmosome, it binds directly to the cytoplasmic tail of the desmosomal cadherins and to the obligate desmosomal protein, desmoplakin (DP). Pg's importance for tissue integrity is evident from the mouse model system where its deficiency leads to late-stage embryonic lethality due to bursting of the ventricles and massive blood leakage from the heart. Disruption in skin cell–cell adhesion also occurs in certain mouse backgrounds. Moreover, Pg mutation in humans results in cardiomyopathy, keratoderma, and wooly hair (Table 1). In addition to its adhesive role, Pg is also thought to function in a variety of signal transduction pathways, including interactions with its family member β -catenin and direct as well as indirect involvement in Wnt signaling pathway. Recently, regulation of Src and Rho pathways as well as regulation of cell–substrate interactions emerged as prominent Pg targets.

The PKPs (PKP1–3) are another group of armadillo family members that contribute to desmosomal adhesion. These proteins have a specific tissue distribution and are differentially expressed in complex stratified epithelia. PKPs are found in the desmosome as well as in the nucleus and messenger RNA (mRNA)-containing stress granules in the cytoplasm. In the desmosome, PKPs interact with the cytoplasmic tails of desmosomal cadherins, Pg, DP, and IFs. The role of individual PKP family members in desmosome assembly and IF attachment has not been completely unraveled; however, PKP1 is thought to enhance the recruitment of DP to the plasma membrane and to facilitate lateral clustering of plaque components. Genetic mutations in both PKP1 alleles negate the protein's function and result in excessive skin fragility (Table 1). Recent findings suggest that PKP2 acts as a scaffold, bringing together molecular components necessary for transport of DP to the membrane. One of the molecules recruited by PKP2 is protein kinase C

Table 1 Human disease associated with desmosomal components

<i>Genetic diseases</i>	<i>Desmosomal molecules mutated</i>	<i>Clinical manifestation</i>
Arrhythmogenic right ventricular cardiomyopathy (ARVC)	Pkp2, DP, Dsg2, Pg, Dsc2	ARVC results in the replacement of right ventricular myocardium with fibro fatty tissue resulting in thinning of the right ventricular wall. Patients die due to sudden cardiac arrest arising from arrhythmia. Some ARVC patients (most notably Pg 188GCA insertion mutation) do not experience any skin symptoms.
Dilated cardiomyopathy (DC)	Dsg2, DP	DC results in ventricular dilation impairing myocardial systolic function resulting in heart failure.
Woolly hair with and without cardiomyopathy	DP, Dsc2, Pg	Woolly hair is a syndrome of the scalp hair and is characterized by frizzy and wiry hair giving it a wool-like appearance. Some patients with Pg mutations develop woolly hair, skin fragility, and diffuse palmoplantar keratoderma without ever developing cardiomyopathy.
Striate palmoplantar keratoderma (SPPK)	DP, Dsg1, Dsc2	SPPK results in the epidermal thickening of the palms and soles and, depending on the genetic background, is often combined with the appearance of woolly hair and cardiomyopathy.
Skin fragility ectodermal dysplasia syndrome	Pkp1	The syndrome results in trauma-induced blistering and subsequent thickening of the skin on palms and soles, abnormal hair, nails and fragile skin which blisters and peels.
Naxos disease	Pg	Naxos disease is a result of combination of ARVC, palmoplantar keratosis and woolly hair.
Localized autosomal hypotrichosis (LAH1)	Dsg4	Sparse, fragile hair with abnormal hair follicles, impaired hair keratinization and epidermal hyperproliferation.
Hypotrichosis and recurrent skin vesicles	Dsc3	Sparse, fragile hair with normal follicles. Recurring skin vesicles prone to bursting and leaving slow healing scars.
Hypotrichosis simplex of the scalp (HTSS)	CDSN (corneodesmosin)	HTSS results in the early hair loss (within the first decade of life) in the patients, with no other skin, hair, or nail symptoms.
Early-onset (type 1a) psoriasis	CDSN	Specific CDSN polymorphisms are strongly correlated with impaired desquamation in the early-onset psoriasis.
<i>Autoimmune diseases</i>	<i>Desmosomal molecules targeted</i>	<i>Clinical manifestation</i>
Pemphigus foliaceus (PF)	Dsg1	PF results in disruption of intercellular adhesion in a cell sheet leading to its acantholysis due to autoantibody against Dsg1. Endemic form of the disease is caused by an as of yet unknown environmental factor.
Pemphigus vulgaris (PV)	Dsg3	PV is a rare blistering autoimmune disease, with anti-Dsg3 antibody and the imbalance between Dsg3 specific helper and regulatory T cells being the cause of the disease.
Paraneoplastic pemphigus	DP and other plakin family members	Severe blistering of the skin and mucous membranes caused by circulating autoantibodies against plakin family proteins. Occurs mainly in the patients suffering from lymphoid malignancies, thymomas and poorly differentiated sarcomas.
IgA pemphigus	Dsg1, Dsg3, Dsc1	Milder form of pemphigus than one caused by IgGs. Neutrophil recruitment to skin by IgA against Dsgs and Dscs causes blistering, with mucosa, palms, and soles usually spared.
<i>Infectious diseases</i>	<i>Desmosomal molecules targeted</i>	<i>Clinical manifestation</i>
Bullous impetigo	Dsg1	Skin infection by group A streptococcus or <i>S. aureus</i> results in the appearance of fluid-filled blisters, usually on the trunk, arms, or the legs. Present mostly in children, spreads by touching.
Staphylococcal scalded-skin syndrome (SSSS)	Dsg1	SSSS results in loss of intercellular adhesion leading to detachment within the epidermal layer. It is caused by the exfoliative toxin produced by <i>S. aureus</i> , but unlike bullous impetigo it has systemic rather than localized effects.

(PKC) α , whose activity is necessary for the modulation of DP interaction with IF and assembly into cell–cell junctions. The importance of PKP2 for maintenance of tissue integrity is emphasized by numerous mutations correlated with congenital arrhythmias such as arrhythmogenic right ventricular cardiomyopathy (ARVC) (Table 1). PKP3 is the most recently discovered and the least studied of the three molecules. Whereas mouse knock-out model system suggests a role in hair follicle morphogenesis and regulation of inflammatory response in skin, some clinical data suggest a larger role for PKP3 in tumorigenesis of several epithelial tumors. PKPs are also engaged in a host of nonadhesive functions which are discussed below.

Plakins

Although desmosomes consist of various components in different tissues, DP, the most abundant protein in the desmosomal plaque, is an obligate desmosomal constituent. DP is the primary plakin family member found in the desmosome, although other less abundant components include envoplakin, periplakin, and plectin. Structurally, the DP molecule consists of two globular ends connected by a coiled-coil rod whose size is modulated by alternative splicing of the transcript to produce two major variants (I and II). The rod domain mediates DP self-dimerization. DP also directly associates with Pg and PKPs through its amino (N)-terminus and with IFs

through its carboxyl (C)-terminus. In addition, direct association of DP with desmosomal cadherin tails has been noted, as has an interaction with PKPs. DP is required for desmosome assembly, linking the IF cytoskeleton to the plasma membrane and anchoring IFs in the plaque. The importance of DP in maintaining tissue integrity is emphasized by the existence of inherited skin diseases of varying severity and cardiomyopathies leading to lethal arrhythmias, caused by mutations in the DP gene (Table 1). In addition to its essential role in desmosomal assembly and IF anchoring, DP is emerging as an important regulator of microtubule organization during epidermal differentiation. DP relocates ninein from centrioles to the sites of cell–cell adhesion, thereby shifting microtubules from radial to cortical organization in the differentiating skin.

Desmosome Assembly and Maintenance

Regulation of the assembly and disassembly of cell–cell junctions is important for normal tissue homeostasis and during junction remodeling processes such as development or wound healing. One crucial factor controlling desmosome assembly appears to be the formation of adherens junctions, which may be required to bring adjacent membranes close together and permit the interaction and clustering of desmosomal molecules. In cultured cells, desmosome assembly occurs in response to cell–cell contact in a calcium-dependent manner. In low calcium conditions, even though they are constantly synthesized and delivered to the plasma membrane, newly synthesized desmosomal components are unstable. Extracellular contact triggers a cascade of calcium-dependent events beginning with the accumulation of E-cadherin and the desmosomal plaque protein, PKP2. PKP2 is required for the accumulation of active RhoA at nascent junctions and associated cortical actin remodeling that drives later stages of desmosome plaque assembly. This process involves the myosin II-dependent translocation of desmosomal precursors containing DP and PKPs to reinforce the plaque. Plaque assembly is spatially and temporally coordinated with clustering of desmosomal cadherins and associated Pg, which are delivered together in vesicles to the plasma membrane. Mature desmosomes are highly insoluble and over time become independent of variations in extracellular calcium concentration. The assembly and maintenance of desmosomes are regulated in part by post-translational modification of protein components. Specifically, serine/threonine and tyrosine phosphorylation of several desmosomal components (including DP) regulates desmosomal assembly and maintenance by modulating the ability of desmosomal proteins to interact with one another.

Desmosome Function

Far from static spot welds, desmosomes are malleable structures which respond to extra- and intracellular signals to adapt their functions in cell–cell adhesion, morphogenesis, and signal transduction.

Cell–cell adhesive function

Although desmosomal cadherins were long assumed to function in calcium-dependent cell–cell adhesion, until recently there has

been a lack of direct evidence demonstrating that ectopically expressed desmosomal proteins promote adhesion in normally nonadherent cells. Evidence now suggests that both Dscs and Dsgs, along with the associated protein Pg, are required for adhesion. Autoimmune, genetic, and bacterial diseases, which affect the desmosomal cadherins and result in compromised epidermal adhesion (Table 1), support the idea that desmosomes function in intercellular adhesion. Intercellular adhesion is also disrupted by human diseases that perturb the structure of the desmosomal plaque (Table 1). Cell-culture models have demonstrated that IF attachment to the desmosome core is a critical aspect in the regulation of desmosome-mediated intercellular adhesion. This is especially important in tissues experiencing mechanical stress such as the skin and the heart, where intercellular adhesive defects can have grave consequences. In particular, several mutations in desmosomal components have been established as a major causative factor in various skin, hair, and nail abnormalities, as well as in congenital heart arrhythmias. Epidermal and heart symptoms may occur independently or in combination and vary in severity from mild to lethal (Table 1). Most notably, according to well-documented studies, ~20% of arrhythmogenic right ventricular cardiomyopathy subjects in Western Europe had a PKP2 mutation.

Morphogenetic function

Analysis of mutations of desmosomal components in animal models highlights the critical role of desmosomes in maintaining tissue integrity during embryonic development beyond the early post-implantation stage. Whereas engineered or spontaneous ablation of desmosomal cadherins, whose expression is primarily restricted to stratified epithelia, results in defects in the structure and function of skin and its appendages, elimination of more generally expressed Dsg2 leads to an early embryonic lethality immediately upon implantation, arguably due to defects in embryonic stem cell proliferation before cell–cell adhesion formation. This observation, combined with the reported pre-implantation mortality of Dsc3-deficient mice, suggests a desmosome-independent role in development for these desmosomal cadherins. DP-deficient mice (growing in the background of DP-expressing extra-embryonic tissues to prevent early adhesive defects) die early during embryogenesis due to numerous problems with heart, skin, and neuroepithelium. Conditional ablation of DP in heart and skin leads to organ-specific abnormalities and may serve as a model system for human DP-related diseases. Null mutations of the armadillo proteins Pg, PKP2, and PKP3 yield animals with lethal cardiac abnormalities (Pg and PKP2), skin fragility (Pg), and hair follicle and skin inflammation impairment (PKP3). Peptide inhibition of desmosomal adhesion has also demonstrated its necessity in normal alveolar morphogenesis by epithelial cells from mammary lumen. Normal desmosomal adhesion is also essential for polarized sorting of aggregated luminal and myoepithelial cells. Desmosome-mediated intercellular adhesion may be intimately involved in many morphogenetic events.

Signaling function

Desmosomes may also have a signaling function. A role in outside-in signaling is evidenced by the ligation of the extracellular domain of Dsg3 and Dsg1 by pemphigus vulgaris

(PV) and pemphigus foliaceus (PF) antibodies, respectively. Whereas PV antibodies sterically hinder cadherin adhesive interactions and PF antibodies do not, both can modulate the intracellular signaling including calcium concentration, phospholipid metabolism, and p38-dependent RhoA activity in keratinocytes. In addition, the antibody-mediated inactivation of RhoA was found to be a significant contributing factor in blistering caused by both autoimmune diseases, presenting itself as a potential therapeutic target. In cultured cells, ligation by PV antibody results in serine phosphorylation of Dsg3 and its reported dissociation from Pg. Pg-null keratinocytes were utilized to demonstrate that PV antibody ligation of Dsg3 leads to a Pg-dependent keratin retraction which may contribute to the epidermal blistering characteristic of this disease.

Intracellular signals can also be propagated by desmosomal components; for example, Pg has been shown to negatively regulate the activity of Src kinase and RhoGTPase family. Although Pg can be found in different junction types, the metabolic stability and cellular localization of Pg are tightly regulated, allowing it to function in cell–cell adhesion as well as in the regulation of cell–substrate interactions. Pg performs these functions through regulation of RNA and protein levels of a variety of extracellular matrix proteins, their integrin receptors, and other cell–substrate adhesion-related molecules. The growing list of regulatory roles of Pg includes transcriptional activation, proliferation, and programmed cell death.

Emerging data suggest the role for other desmosomal molecules in the regulation of intracellular signaling, including functional interactions between PKP2 and PKC α as well as the role of Dsg1 in the inhibition of EGFR/Erk signaling. Intriguingly, PKP1 and PKP3 are found in complexes with RNA-binding proteins as well as in stalled translation initiation complexes (stress granules) and, in the case of PKP1, are shown to directly stimulate

translation through activation of eIF4A1 translation initiation factor. These exciting findings point toward a broad regulatory role of desmosomal component in many critical processes in the cell beyond their function as adhesive molecules.

The Hemidesmosome

Hemidesmosomes are specialized junctions that connect basal epithelial cells to the basement membrane and underlying extracellular matrix. Hemidesmosomes promote the integrity and strength of epithelial tissues by indirectly connecting the intracellular keratin IF cytoskeleton to extracellular matrix proteins.

Hemidesmosome Ultrastructure

The ultrastructure of the hemidesmosome (Figure 2, left) includes an electron-dense cytoplasmic triangular plaque, which comprises an inner IF-rich region closest to the cell cytoplasm and a perimembrane plaque containing the cytoplasmic tails of the transmembrane hemidesmosome components. Just adjacent and external to the basal cell membrane is a sub-basal dense plate and thin, extracellular anchoring filaments that extend from the plate into the specialized extracellular matrix of the basement membrane.

Structure and Molecular Components of the Hemidesmosome

The major hemidesmosomal components together connect the basal epithelial cell cytoskeleton to the extracellular matrix (Figure 2, right). Hemidesmosomal proteins are arranged such that IFs are anchored to the plaque at multiple points, re-enforcing the connection to the substratum.

Figure 2 Molecular composition and structure of the hemidesmosome. (Left) Hemidesmosome ultrastructure is shown in this electron micrograph of bovine tongue epidermis. (Right) Hemidesmosomal proteins, their interactions, and their approximate position within the organelle are depicted in this schematic diagram of the hemidesmosome. Reproduced from Jones JCR, Yokoo KM, and Goldman RD (1986) Is the hemidesmosome a half desmosome? An immunological comparison of mammalian desmosomes and hemidesmosomes. *Cell Motility and the Cytoskeleton* 6: 560–569.

$\alpha 6 \beta 4$ integrin

The $\alpha 6 \beta 4$ integrin heterodimer is essential for hemidesmosome formation and maintenance of epithelial cell attachment to the basement membrane. The $\alpha 6 \beta 4$ integrin is a receptor for the matrix protein laminin-332, and its interaction with laminin-332 is thought to be the structural center of the hemidesmosome. The $\alpha 6 \beta 4$ integrin heterodimer is expressed predominantly in epithelial tissues, Schwann cells, and endothelial cells. The $\beta 4$ integrin subunit has an unusually long cytoplasmic tail, which is important for the specialized functions of this molecule and for interaction with the other hemidesmosomal proteins plectin, type XVII collagen, and BPAG1e. The interaction with plectin is thought to stabilize the association of $\alpha 6 \beta 4$ integrin with laminin-332 to enhance adhesion strength.

Type XVII collagen (BPAG2, BP180)

Type XVII collagen is a 180-kDa type II transmembrane protein component of the hemidesmosome. It was originally named bullous pemphigoid antigen II (BPAG2) or BP180 because autoantibodies from the serum of patients with the severe blistering disease bullous pemphigoid recognize and bind to this protein (Table 2). Type XVII collagen is a trimer that contains collagen-like repeats in its C-terminal extracellular domain which organize into a triple helical coiled coil. Type XVII collagen interacts with the $\beta 4$ integrin subunit and the hemidesmosomal protein BPAG1e through its N-terminal domain, and with the $\alpha 6$ integrin subunit via its C-terminal extracellular domain. The latter interaction seems to be

essential for hemidesmosome formation and stabilization. Although type XVII collagen can bind almost all the proteins within the hemidesmosome, its major function appears to be recruitment of BPAG1e to the hemidesmosome. Type XVII collagen is also known to interact with actinin family members and to co-distribute at sites of cell–cell contact with adherens junction proteins, suggesting a potential role for this molecule in mediating cross-talk between cell–substrate and cell–cell junctions.

BPAG1 (BP230)

Bullous pemphigoid antigen I (BPAG1 and BP230) is a 230-kDa plakin family member that, like type XVII collagen, was first identified as a protein recognized by autoantibodies of patients with bullous pemphigoid. Four main splice isoforms of BPAG1 have been identified. The epithelial specific form (BPAG1e) is a cytoplasmic plaque component of the hemidesmosome. BPAG1e is known to interact with IFs through its C-terminus, whereas the N-terminal domains interact with the $\beta 4$ integrin subunit and type XVII collagen. BPAG1e is thought to link the keratin IFs to type XVII collagen and the hemidesmosomal plaque. Skin isolated from BPAG1-null mice has poorly formed hemidesmosomes with few filament attachments.

Plectin

Plectin, also referred to as IFAP 300 or HD1, is a 500-kDa plakin family member. It is particularly important for hemidesmosome function in epithelial tissues, and as a cytoplasmic

Table 2 Human disease associated with hemidesmosomal components

<i>Genetic diseases</i>	<i>Hemidesmosomal molecules mutated</i>	<i>Clinical manifestation</i>
Herlitz or non-Herlitz junctional epidermolysis bullosa (JEB)	Laminin-332, $\beta 4$ integrin	Herlitz: Autosomal recessive: severe blistering at the dermal–epidermal junction often coincident with early mortality. non-Herlitz: Less severe form, often includes lifelong blistering, but improves with age, loss of hair and nails, and dental abnormalities.
Junctional epidermolysis bullosa with pyloric atresia (JEB-PA)	$\alpha 6$ or $\beta 4$ integrin	Mucocutaneous blistering associated with congenital intestinal abnormalities.
Dystrophic epidermolysis bullosa (DEB)	Collagen VII	The most severe form of epidermolysis bullosa characterized by deep blistering in dermis due to disruption of anchoring fibril stability.
Non-Herlitz JEB/generalized atrophic benign epidermolysis bullosa (GABEB)	BPAG2 (BP180)	Autosomal recessive generalized skin blistering with mild scarring, nail dystrophy, enamel hypoplasia, pigmentary changes, and hair loss.
Epidermolysis bullosa with muscular dystrophy (EB-MD)	Plectin	Skin blistering noted from birth with late-onset, progressive muscle weakness.
<i>Autoimmune diseases</i>		
	<i>Hemidesmosomal molecules targeted</i>	<i>Clinical manifestation</i>
Bullous pemphigoid	BPAG1, BPAG2	Generalized large subepidermal blisters caused by circulating autoantibodies against Type XVII Collagen (BPAG2, BP180) and BPAG1e (BP230).
Cicatricial pemphigoid	Laminin-332, BPAG2	Chronic subepithelial blistering of mucous membranes and, occasionally, of the skin. Caused by circulating autoantibodies against laminin-332 or type XVII collagen.
Ocular cicatricial pemphigoid	$\beta 4$ integrin	Subset of mucous membrane pemphigoid. Subepithelial blistering that mainly affects conjunctiva more than other mucous membranes. Leads to ocular keratinization, corneal scarring and blindness. Caused by circulating autoantibodies against $\beta 4$ integrin.
Oral Pemphigoid	$\alpha 6$ integrin	Subset of cicatricial pemphigoid. Blistering limited to oral cavity. Caused by circulating autoantibodies against $\alpha 6$ integrin.
Epidermolysis bullosa acquisita	Collagen VII	Minor skin trauma induces severe blistering below the dermal–epidermal junction. Caused by circulating autoantibodies against collagen VII.

cytoskeletal linker in other tissues, but has also been reported in less abundance in desmosomes. Plectin's importance for hemidesmosome stability and tissue integrity is emphasized in patients with genetic mutations in the plectin gene who suffer from severe skin blistering and muscular dystrophy (Table 2). Plectin can interact with itself, with IFs, and with multiple domains of the $\beta 4$ integrin tail. Plectin has been proposed to cluster $\alpha 6\beta 4$ molecules at the basal cell surface, a potentially critical step in the formation of hemidesmosomes. However, the primary role for plectin (like BPAG1) is to link the IF system to the hemidesmosome plaque, stabilizing the junction by connecting the IF cytoskeleton to the hemidesmosome core at multiple points.

CD151

CD151, a member of the tetraspanin family, has been recently identified as a component of the hemidesmosome. The $\alpha 6$ integrin subunit and CD151 interact directly, and, thus, CD151 appears concentrated at hemidesmosomes. The exact function of CD151 as a hemidesmosomal component requires further investigation, since the skin of mice lacking CD151 contains normal hemidesmosomes.

Laminin-332

Laminin-332 (previously laminin-5) is a member of the laminin family of large, heterotrimeric glycoproteins, which are major constituents of extracellular matrices. Laminin-332 is necessary for the firm attachment of basal epithelial cells to the subepithelial basement membrane by linking the hemidesmosome to the underlying tissue. In the hemidesmosome, laminin-332 binds to $\alpha 6\beta 4$ integrin to mediate cell–substrate attachment. Laminin-332 is highly expressed in many types of epithelia and is specifically composed of subunits $\alpha 3$, $\beta 3$, and $\gamma 2$, which interact in a noncovalent fashion to form a cross-shaped structure. The subunits of laminin-332 undergo proteolytic processing after the molecule is secreted into the matrix. Yet, laminin-332 is initially secreted in an unprocessed form. This precursor laminin-332 is thought to promote cell migration, whereas cleavage of the $\alpha 3$ subunit promotes hemidesmosome nucleation and stable adhesion in an $\alpha 6\beta 4$ integrin-dependent manner. Laminin-332 is also known to mediate epithelial cell attachment through the nonhemidesmosomal integrin $\alpha 3\beta 1$. Laminin-332 strongly attaches epithelial cells to the extracellular matrix by interacting with other basement membrane proteins, including type VII collagen. Genetic or autoimmune diseases involving laminin-332 are characterized by complete separation of the epidermis from the dermis (Table 2) and further support an important role for laminin-332 in the attachment of basal epithelial cells to the underlying basement membrane.

Hemidesmosome Assembly and Maintenance

The nucleation and assembly of hemidesmosomes depend upon the phosphorylation state of $\alpha 6\beta 4$ integrin and laminin-332. It has been suggested that laminin-332 induces clustering of $\alpha 6\beta 4$ integrin, followed by recruitment of plectin, BPAG1e, and type XVII collagen to the nucleation site. In addition, clustering of the $\alpha 6\beta 4$ integrin has been shown to promote phosphorylation of the $\beta 4$ integrin subunit

cytoplasmic tail and hemidesmosome assembly. The $\alpha 3\beta 1$ integrin is also suggested to be an initiator of hemidesmosome assembly, by forming pre-hemidesmosome clusters of CD151, $\alpha 3\beta 1$ integrin, and laminin-332. These clusters have been proposed to serve as docking sites for $\alpha 6\beta 4$ integrin.

Both bullous pemphigoid antigens are also thought to be important players in regulating hemidesmosome assembly. Patients with mutations in the type XVII collagen gene have normal $\alpha 6\beta 4$ integrin and laminin-332 localization but absent or underdeveloped hemidesmosomes. In addition, overexpression of BPAG1e in cells alters the localization of endogenous type XVII collagen, suggesting a role for BPAG1e in initiating early interaction of some hemidesmosome proteins prior to junctional incorporation.

Laminin-332 also contributes to the regulation and maintenance of hemidesmosomes. Processing of laminin-332 promotes hemidesmosome formation, as mentioned above. For adhesion, laminin-332 appears to initially interact with $\alpha 3\beta 1$ integrin to mediate attachment of the epithelial cells to the extracellular matrix. Ligation is then transferred to $\alpha 6\beta 4$ integrin for long-term, stable adhesion.

Hemidesmosome Function

Hemidesmosomes were long thought to be inert adhesive structures with primary importance in maintaining and stabilizing epithelial cell attachment to the underlying basement membrane. However, recent evidence suggests that the proteins that comprise these structures exhibit dynamic characteristics that may facilitate tissue remodeling processes during development and wound healing as well as permit rapid responses to extracellular signals.

Cell–substrate adhesive function

A structural function for hemidesmosomes in initiating and maintaining adhesion between basal epithelial cells and the extracellular matrix is well accepted today, in part because of evidence from autoimmune and genetic human skin diseases which result in epithelial cell–basement membrane separation and severe blister formation (Table 2). Other evidence supporting this structural role comes from the noted absence of hemidesmosomes in cells closing wounds and in invasive epithelial tumor cells. Thus, hemidesmosomes appear necessary for stable anchorage of cells to the basement membrane but may not be required in motile cells.

Morphogenetic function

The role that hemidesmosomes play in morphogenetic events such as breast epithelial tubule formation indicates the relative dynamic nature of these structures *in vivo*. Indeed, perturbation of the microfilament cytoskeletal architecture in cultured cells results in a redistribution of IF-tethered hemidesmosomes to the cell periphery, highlighting the dynamic nature of the hemidesmosome plaque and its ability to move laterally within the cell membrane.

Transmembrane signaling function

The proteins that comprise the hemidesmosome are important mediators of signal transduction; however, they activate signaling cascades when not assembled into a complete

hemidesmosome adhesion device. Furthermore, $\alpha 6 \beta 4$ integrin, the hemidesmosomal protein mainly involved in mediating signaling, can act in a ligand-dependent and -independent manner. The $\alpha 6 \beta 4$ integrin appears to be able to activate a number of signaling cascades, including the phosphoinositide 3-OH kinase (PI3K), mitogen-activated protein kinase (MAPK), c-jun N-terminal kinase (JNK), and small guanosine phosphatase (GTPase) Rac pathways. Therefore, in addition to promoting cell adhesion, the $\alpha 6 \beta 4$ integrin functions to promote cell migration, invasion, proliferation, and survival. Phosphorylation of specific tyrosine residues within the large cytoplasmic tail of the $\beta 4$ integrin subunit leads to activation of the distinct signaling pathways and subsequent cellular processes.

Although it is well accepted that $\alpha 6 \beta 4$ integrin and its ligand laminin-332 are essential for stable anchorage of cells to the extracellular matrix, there is emerging evidence that they also mediate the migration of cells – this is controversial. Nonetheless, studies investigating wound healing or tumor cell migration indicate that $\alpha 6 \beta 4$ integrin is localized at the leading edge of the lamellipodium, where it signals to activate Rac1 and the actin-severing protein cofilin. In addition, laminin-332 has been shown to be deposited at the leading front of migrating cells, suggesting that it provides a track upon which the cell can move. This mechanism is proposed to be $\alpha 6 \beta 4$ integrin dependent. Although direct evidence for $\alpha 6 \beta 4$ integrin as the main mediator of cell migration is lacking, several models have been proposed in which $\alpha 6 \beta 4$ integrin serves a dual function, that is, one of stable attachment in the confines of the hemidesmosome and the other as a mediator of cell migration when the hemidesmosome is disassembled.

Despite their ultrastructural and functional similarity as adhesive junctions, desmosomes and hemidesmosomes are unique structures. Significant progress has been made thus far in the fields of desmosome and hemidesmosome research. The structural organization of these junctions has been examined. Molecular components that comprise these junctions have been identified. Protein–protein interactions that contribute to the normal function of these organelles have been characterized. Future studies in these fields will likely focus on a growing array of nonadhesive functions for protein components of these junctional complexes, and their underlying signaling cascades.

Glossary

Aggregation number Number of detergent molecules in the average micelle.

Critical micelle concentration (CMC) Concentration of detergent in aqueous solution above which micelles begin to form, essentially the maximum concentration of detergent in monomeric form.

Detergent A compound having spatially segregated hydrophilic and hydrophobic regions and which, when dissolved in water above the CMC, self-associates to form micelles.

Hydrophilic group Structure having an affinity for water with strong favorable noncovalent bonds with water molecules.

Hydrophobic group Structure exhibiting an aversion to water and preference for hydrocarbon-type liquids.

Micelle Structure formed by the noncovalent and highly cooperative self-association of a detergent molecule so as to form a hydrophobic core from which the hydrophilic groups project into the aqueous surroundings.

A molecule can be classified as a detergent when within its chemical skeleton one can identify spatially segregated regions, one with an affinity for water (a hydrophilic group) and one which, on its own, would have limited water solubility (a hydrophobic group). For well-behaved detergents in aqueous solution, this molecular polarity drives the formation of a mixture consisting of monomeric detergent molecules in equilibrium with a fairly monodisperse population of detergent aggregates known as 'micelles'. In the micelle, the hydrophobic groups are packed together to create a hydrophobic core with the attached hydrophilic groups projecting out from the surface of this core and protecting it from contact with water. To date, only limited biological functions for detergents have been identified such as the well-known role in digestion and possibly, to some extent, in membrane fusion events; however, they play necessary if not essential roles in the isolation, manipulation, and characterization of the constituents of biological membranes.

Chemical Structure of Detergents

The chemical structures of detergents which have been employed in biological studies are quite varied and continue to grow as investigators attempt to develop new entities that will permit the facile isolation of membrane constituents while enhancing their stability once isolated. To reach this goal, various combinations of hydrophobic and hydrophilic groups have been utilized which yield a variety of physical and chemical properties.

Hydrophobic Groups (Tails)

Simple hydrocarbon chains

The hydrocarbon chain is the most easily recognized hydrophobic group and when present is often referred to as the molecule's 'hydrophobic tail' (Figure 1). These chains are most often saturated hydrocarbons (Figure 1) and are

available in many lengths. The shorter the chain the less well defined the detergent properties tend to be, whereas longer tails become essentially insoluble. Unsaturation and more complex branching structures have been explored, as well as chains incorporating phenyl rings. The presence of the ultraviolet light-absorbing phenyl ring should generally be avoided as it can complicate various spectroscopic techniques.

Ring-based hydrocarbons

The naturally occurring bile salts synthesized from cholesterol and utilized in digestive processes are the prototypes for detergents based on ring systems. Figure 1 shows cholic acid, one of the abundant bile salts which is converted to deoxycholate (DOC) by removing the hydroxyl at the arrow. Identifying the spatial segregation of the hydrophilic and hydrophobic groups in these detergents may require careful inspection of their three-dimensional chemical structure. In cholic acid, the carboxyl group is an obvious hydrophilic group, but the effects of the hydroxyl groups located on the rings must also be considered. Viewing the steroid ring nucleus in the molecule as defining a plane, the spatial arrangement of the hydroxyls creates a hydrophilic face on one side and a hydrophobic face on the other side of this plane. The structure of DOC suggests the presence of only a hydrophilic edge along the ring plane, making the whole structure more hydrophobic than cholic acid, which may explain why DOC is generally a more aggressive solubilizer than cholic acid.

Hydrophilic Groups (Headgroups)

Ionic

Positively (e.g., amino) and negatively (e.g., carboxyl) charged groups have been utilized as hydrophilic groups. Single-tailed ionic detergents tend to denature all proteins, with the anionic ones being more aggressive denaturants than cationic molecules. One of the most familiar examples is the anionic detergent, sodium dodecyl sulfate, NaDodSO₄ (Figure 1). It is the denaturing effect of NaDodSO₄ on proteins that led to the

used when relatively freshly prepared; moreover, when using commercial sources one should be aware that antioxidants are sometimes included.

Connecting Head and Tail

Linkages between the hydrophobic and hydrophilic groups are most often either an ether or ester linkage. The latter can be susceptible to hydrolysis, especially in biological preparations, which in turn could generate an ionic group with denaturing properties.

Detergent Properties

Critical Micelle Concentration

The most common concentration-dependent behavior for detergents is illustrated in **Figure 2**. The monomer concentration increases until the critical micelle concentration (CMC) above which an equilibrium is established between the monomer and an increasing concentration of micelles. For well-behaved detergents, the monomer concentration increases very little after reaching the CMC and thus is in effect the highest possible concentration of monomeric detergent. All detergents in excess of the CMC are incorporated into micelles (dashed line in **Figure 2**). The concentration of micelles increases linearly with total detergent concentration above the CMC, but at a slower rate since a large number of molecules are incorporated into each micelle. Some detergents exhibit more complex behavior, such as secondary association of micelles or even new phases as the total concentration continues to increase.

As illustrated in **Figure 2**, the CMC is actually a narrow range of concentration over which the formation of micelles becomes dominant. Nonetheless, a single number is usually defined as the CMC and determined by plotting some physical observable whose response differs markedly above and below the CMC against the total concentration of detergent. The CMC is then taken as the intersection of lines extrapolated from the nearly linear regions above and below the transition as shown

Figure 2 Concentration-dependent behavior of a detergent. The calculations are based on the theory of micelle formation developed by Tanford. An aggregation number of 50 was used and the equilibrium constant for micellization was chosen to yield the critical micelle concentration (CMC) indicated.

by the dotted lines in **Figure 2**. Using different observables or concentration ranges for the extrapolation can lead to somewhat different values for the CMC. One of the simplest methods to measure a CMC is the spectrophotometric monitoring of the solubilization of heme, which is essentially insoluble below the CMC and increases as the concentration of micelles increases; the increase in absorbance with detergent concentration would be similar to the dashed line in **Figure 2**.

CMCs range from nanomolar to several millimolar. For single-tailed detergents, the CMC decreases with increasing length of tail and with smaller headgroups. The CMC of nonionics is generally lower than that of ionics with the same length of tail. Ionic headgroups are more susceptible to solution variables than are nonionics. Ionic headgroups that can be titrated are sensitive to pH and may precipitate when the headgroup is in neutral form (both cholic acid and DOC are examples). The CMCs of ionics may also be influenced by the type and concentration of counterions present, for example, using potassium instead of sodium for dodecyl sulfate results in an insoluble salt. In general, higher salt concentrations will decrease the CMC of an ionic detergent which is a consequence of reducing the headgroup repulsion in the micelle. Even the POE-based nonionics may be influenced by presence of salts as the ether groups are capable of at least weakly complexing ions. The solubilization of other components in the micelle (e.g., mixed micelles with lipids) will generally decrease the CMC (i.e., the maximum monomer detergent concentration is decreased). Published values of CMCs are useful guides in experimental design, but should generally be confirmed under the actual experimental conditions.

Aggregation Number

Micelles are formed as a result of a highly cooperative self-association process in which many detergent molecules form a single noncovalent structure. While the number of molecules in each micelle is somewhat variable, the average number of molecules per micelle (aggregation number) can be determined by standard hydrodynamic methods (e.g., sedimentation equilibrium). The aggregation number is needed to calculate the micelle concentration, which is the total detergent concentration in excess of the CMC divided by the aggregation number. This allows one to be certain that the number of micelles to protein chains is high enough so as to minimize the possibility of adventitious association between protein chains.

The CMC transition becomes sharper as the aggregation number increases. The CMC is generally strongly dependent on the size of the hydrophobic moiety, but repulsion between headgroups is the dominant factor for the aggregation number. Thus, nonionics tend to have larger aggregation numbers than ionics of the same tail length. The aggregation number for ionic detergents can be strongly influenced by both the type and concentration of counterions present as well as pH since these factors can dramatically change the electrostatic repulsion between the charged headgroups. Longer hydrophobic tails tend to have larger aggregation numbers. Detergents with high CMCs tend to have more variability in their micelle size distribution. At high concentrations and under certain solution conditions (e.g., elevated temperature), larger

structures may be formed which in some cases are new micellar phases and in others simply secondary aggregation of smaller micelles.

Temperature Effects

As a thermodynamic equilibrium, the formation of micelles can be influenced by temperature. At low enough temperatures, solid detergent will exist in equilibrium with monomeric detergent; as the temperature increases, the monomer concentration increases until it reaches the CMC at the critical micelle temperature. Above this temperature, solid detergent will begin to go into solution as micelles. The temperature at which solid, micelles, and monomeric detergent at the CMC coexist is called the 'Kraft point' and for most detergents is the same as the critical micelle temperature. An often-observed Kraft point, which is near room temperature, is that of sodium dodecyl sulfate where upon cooling one sees precipitation of detergent. A second temperature effect observed at higher temperature, especially with nonionics containing POE, is the cloud point. Above the CMC at this temperature, the solution will turn turbid due to the formation of much larger aggregates. Both the critical micelle temperature and cloud point have been exploited in purification of membrane components.

Micelle Structure

Single-Tailed Detergents

In a typical micelle, the hydrophobic tails are sequestered into a central core structure with the hydrophilic groups projecting out from the surface of this core into the aqueous surrounding. The tails in the core are not fully extended but are quite flexible, some even lying along the surface of the core rather than within it. The surface of the core should be regarded as having a rippled texture with some tail methylene groups protruding above it. Experimental and theoretical arguments suggest that for most detergent micelles the overall shape is best described as an oblate ellipsoid, although for small aggregation numbers the shape cannot be readily distinguished from spherical. For $C_{12}E_8$ micelles (Figure 1), theoretical calculations constrained by hydrodynamic measurements yield an oblate ellipsoid with dimensions shown in Figure 3. Since the core cannot contain a void, one dimension must be less than the 3.4 nm length of two fully extended 12C chains. For the same length of tail, the overall dimensions of the micelle will depend on the nature of the headgroup. For POE-based detergents, the headgroup is in a random-coil configuration and consequently occupies a very large region of the space surrounding the core, as suggested in Figure 3.

Figure 3, while a convenient visualization of micelle structure, cannot convey the highly dynamic processes occurring. Detergent molecules are rapidly exchanged among micelles; whole micelles disappear and reform with slightly different aggregation numbers. The hydrophobic core acts for the most part like a simple liquid hydrocarbon with the tails constantly flexing. POE headgroups occupy a great deal of space around the core and are constantly changing their conformation as well. Finally, it should be obvious that the type and size of headgroup can generate dramatically different chemical

Figure 3 Shape of micelles formed by typical single-tailed detergents. The model shown is based on data and calculations for $C_{12}E_8$. The dimensions shown are in nm.

environments to which molecules solubilized by detergents are exposed; moreover, the solution composition near a micelle may be quite different from that of the bulk aqueous solution.

Ring-Based Detergents

Bile salts usually have relatively high CMCs and quite small aggregation numbers (4–10). The small aggregation number does not permit micelles as just described. The micelles are more heterogeneous and are probably best viewed as small assemblies with the hydrophobic surfaces facing each other, presenting their hydrophilic faces to the surrounding solution. The size and shape of these micelles are quite sensitive to the concentration and types of ions, and potentially pH.

Detergents as Tools in Membrane Studies

Membrane Solubilization

Initially, when a membrane is exposed to detergent, monomers partition into the bilayer, so one can imagine that a high CMC might be advantageous (e.g., OG has a very high CMC (>15 mM) and is an efficient solubilizer). As more detergent intercalates into the membrane bilayer, one reaches a stage where fragmentation occurs, resulting in large mixed micelles containing detergent, lipids, and proteins in various ratios. Continuing to add detergent will eventually disperse the membrane components to the point that any given micelle contains no more than a few lipids, a protein, or the detergent alone. One can apply isolation and enrichment techniques for specific targets to this solubilized mix. The choice of detergent can hinder or help in isolation, for example, a small aggregation number can facilitate separation of a large protein-containing micelle from those containing only lipid components. It is possible, and perhaps even desirable, to exchange detergents, so that one detergent might be used to speed initial membrane

solubilization and another for final isolation of a stable target. It is important to recognize that it is the concentration of micelles that needs to be controlled when one is studying membrane components solubilized by detergents, and generally one should maintain a ratio of several micelles to each solubilized component to avoid the possibility of spurious associations.

Membrane Proteins

A detergent can be found that can reasonably mimic the properties of the hydrophobic core of a native membrane environment. However, the membrane itself provides a physical constraint to a protein embedded within it, in that the protein cannot expand laterally in the plane of the membrane nor can it pull itself through the bilayer; in a detergent solution, such a physical constraint is greatly relaxed and the protein in effect has a much expanded conformational space including conformations where activity will be lost possibly irreversibly. Low CMCs and large aggregation numbers may partially compensate for the loss of the membrane's physical constraints. In addition, the native membrane environment provides a multitude of diverse interactions with a variety of lipid headgroups, tails, and with other proteins and, moreover, these interactions may differ from one side of the membrane to the other. The roles of these types of interactions in maintaining an active protein are not well understood, and they are radically changed or even eliminated upon solubilization. Studies as a function of micelle concentration should be performed, as there is always a possibility of adventitious interactions, due merely to the fact that too few micelles are present.

Reconstitution of Protein into a Bilayer

Many of the functions of membrane proteins are vectorial in nature, and one must for full characterization eventually reconstitute the protein into a lipid bilayer where these functions can be probed. Starting with mixed micelles of protein in detergent and lipids in detergent, one must effect a controlled removal of the detergent, permitting the formation of an artificial membrane bearing the protein. This is accomplished largely by trial and error. A high CMC permits the use of dialysis since the monomer should pass through the dialysis membrane. Hydrophobic beads to which the detergent absorbs have also proven effective in reconstitution studies.

Summary

Obviously single-tailed ionic detergents should generally be avoided because of their potential to denature any protein. While zwitterionic headgroups can be identical or at least similar to those of native lipids, to date they have not proven any more useful than others. High CMC detergents may be better choices for initial solubilization and eventual reconstitution. But long tails and large headgroups (usually accompanied by a low CMC) may enhance stability by restricting the conformational space accessible to the protein while in the detergent solution. The requirements for efficient solubilization and for the maintenance of activity may to a large extent be antagonistic. The possibility of using one detergent to solubilize and subsequently exchanging into another to enhance stability for isolation and study is always worth consideration. The thermodynamic interactions resulting from the dissolution of a protein in a detergent solution are complex and require great care when evaluating stability and functional data. One must recognize that the thermodynamic properties of all the components of the solution (protein, detergent, buffer, salts, etc.) are inextricably linked together (via the Gibbs–Duhem relationship) so that a simple change in salt concentration may appear to have altered a protein's stability, but in reality did so only indirectly via a change in some property of the detergent. Unfortunately, there is no perfect detergent for all situations, nor are there hard-and-fast rules for choosing a detergent for a specific task. In the end, the choice is still largely a matter of trial and error.

Glossary

β -Cell The insulin-producing cells in the Islets of Langerhans.

Glucose disposal The removal of glucose from the blood, usually in the context of its removal after having been added, as after absorption of a carbohydrate-containing meal.

Glucose intolerance The condition where the concentration of glucose in the blood after ingestion of carbohydrate is elevated above normal; it may also refer more generally to a condition associated with hyperglycemia.

Hyperglycemia An abnormally elevated concentration of glucose in the blood.

Kinase An enzyme that modifies a substrate through the addition of a phosphate group.

Osmotic diuresis An increase in urine output stimulated by an increase in osmotically active solute in the urine; in diabetes, the solute is glucose.

Phosphatase An enzyme that modifies a substrate through the removal of a phosphate group.

Prandial Meal associated.

Introduction

The defining feature of diabetes mellitus is an abnormal elevation of the blood glucose level. When the degree of hyperglycemia is mild, there may be no symptoms of diabetes. With greater degrees of hyperglycemia, the concentration of glucose in the blood exceeds the ability of the kidneys to completely reabsorb the glucose delivered to it. The resultant loss of glucose in the urine provides an osmotic force that draws increased water into the excreted urine, causing the patient to experience polyuria (increased urination; this glucosuria gives diabetes mellitus its name, which can be translated from the Greek as 'sweet urine' or more directly as 'honey siphon'). The osmotic diuresis from glucosuria induces polydipsia (increased drinking) in order to prevent dehydration. When uncontrolled, diabetes mellitus puts patients with these diseases at risk of acute metabolic decompensation, particularly when the insulin deficiency is complete, as in type 1 diabetes mellitus. While this decompensation is life threatening, since the introduction of insulin treatment over 80 years ago these events are generally preventable. It is now the long-term complications that all patients with diabetes mellitus are at risk that has become the most significant burden. Due to these long-term complications, diabetes is a leading cause of blindness and end-stage renal disease. In addition, diabetes is associated with accelerated atherosclerotic vascular disease, leading to a risk of myocardial infarction, stroke, and limb amputation that is increased and occurs at a younger age than in those without diabetes.

Etiology

For each type of diabetes mellitus, the relative contribution of a defect in insulin secretion versus a defect in insulin action will vary. For example, the two most common forms of diabetes are type 1, which is due to an isolated deficiency in insulin, and

type 2, which is due to varying degrees of insulin resistance and deficient insulin secretion. In addition, some forms of diabetes have a predominantly genetic etiology, such as the group of autosomal dominantly inherited forms of diabetes known collectively as maturity-onset diabetes of the young (MODY), whereas in other types both genetic and environmental factors are important, exemplified by type 2 diabetes, where the development of obesity is a significant contributor to the cause of insulin resistance that is central to the pathophysiology of this disease.

Type 1 Diabetes Mellitus

Type 1 diabetes accounts for ~5–10% of all cases of diabetes. It typically has its onset in childhood, although it can occur at any age. Type 1 diabetes is due to the destruction of the insulin-producing β -cells of the pancreas, resulting in an absolute deficiency of insulin. In the vast majority of cases, the destruction is due to a cell-mediated autoimmune attack of the β -cells. This process appears to be precipitated by environmental factors in genetically susceptible individuals. While viral infections, dietary components, and specific toxins have been suspected, the true identity of the environmental triggers remains unknown. About half of the genetic portion of the risk lies in the immune-recognition genes of the HLA locus. Variants in at least 16 other genetic loci also affect risk for type 1 diabetes. Several variants are also thought to act through the immune system; some of these diabetes risk variants operate in other autoimmune diseases including multiple sclerosis and autoimmune thyroid disease.

In almost all cases of type 1 diabetes, there is ultimately near complete destruction of the pancreatic β -cells. Because of this, these patients are dependent on treatment with exogenous insulin for their survival, as the absence of such treatment leads to rapid metabolic deterioration into diabetic ketoacidosis (DKA) and death.

Type 2 Diabetes Mellitus

Over 90% of diabetes is due to type 2 diabetes. The prevalence of this disease increases with age; previously, it had been uncommon for children or young adults to be diagnosed with this disease. However, there has been a recent dramatic increase in the prevalence of this disease, and with this, significant numbers of children are now being diagnosed with type 2 diabetes. Although much has been learned about the pathophysiology of type 2 diabetes in the past few decades, there remains much to be learned about the specific details of its cause. What is known is that two defects are present in patients with type 2 diabetes: insulin resistance and defective insulin secretion. Insulin resistance refers to a decreased effectiveness of insulin in activating signals distal to binding of insulin to the insulin receptor. Insulin resistance itself, except in the most extreme situation, will not lead to diabetes, as normal metabolic control can be maintained by a compensatory increase in insulin secretion. When a second defect results in an inability to respond to the requirement for increased insulin secretion imposed by insulin resistance, type 2 diabetes mellitus occurs.

There is strong familial clustering of type 2 diabetes, and the risk for this disease varies considerably across different ethnic populations. These and other findings indicate that there is a strong genetic component to the development of type 2 diabetes. However, multiple genes appear to be involved, with each individual with diabetes having altered function of multiple gene products. In addition, the relative contribution of insulin resistance versus defective insulin secretion can vary from patient to patient, so that there is likely a subset of altered genes contributing to the development of type 2 diabetes that differs from one person to the next. The genes involved include those encoding proteins affecting insulin signaling and insulin secretion, those controlling metabolic pathways, and those contributing to the development of obesity.

Environmental factors play a significant role in determining which genetically predisposed individuals will develop type 2 diabetes. Obesity and low levels of physical activity are strongly associated with insulin resistance, and are the factors to which the rising prevalence of type 2 diabetes in industrialized societies is ascribed. In addition, insulin sensitivity (the inverse of insulin resistance) decreases with age, accounting for much of the increased prevalence of this disease with increasing age.

Insulin resistance

Both central (hepatic) and peripheral (muscle and adipose) defects contribute to the insulin resistance of type 2 and obesity. (Interestingly, experiments in rodents have indicated that resistance in cells not classically characterized as being insulin responsive, including the brain and pancreatic β -cells, may contribute to the pathophysiology of obesity and type 2 diabetes.) Hepatic insulin resistance results in increased glucose output from the liver, predominantly due to increased gluconeogenesis. Insulin-resistant muscle and adipose cells have diminished insulin-stimulated glucose uptake, and the muscle cells have a marked decrease in glycogen synthesis. These defects, particularly in the muscle, result in decreased disposal of glucose after a meal. In addition, the decreased metabolism

of glucose to glycogen leads to increased glycolysis and production of lactate, which circulates to the liver and provides substrate for increased gluconeogenesis. The increased hepatic glucose production contributes most to fasting hyperglycemia, while the decreased glucose disposal into muscle contributes most to postprandial hyperglycemia.

Although the mechanisms remain incompletely understood, a number of factors have been demonstrated to contribute to the insulin resistance of type 2 diabetes, including free fatty acids and other factors secreted by adipocytes, as well as hyperglycemia itself (Figure 1). Free fatty acids impair insulin sensitivity, both in the liver and in muscle, and increased circulating levels of free fatty acids are found in obese and insulin-resistant subjects, due to increased lipolysis in adipocytes. Importantly, intra-abdominal fat tissue has a higher lipolytic rate compared to subcutaneous adipose tissue, and excess intra-abdominal adiposity has a much higher association with insulin resistance than obesity with a more peripheral (subcutaneous) distribution. Abnormal secretion by the adipocyte of a number of other factors (adipokines) has also been implicated in the pathophysiology of insulin resistance, including tumor necrosis factor α (TNF- α), resistin, adiponectin, and leptin. Hyperglycemia itself causes impaired insulin sensitivity. This may be due to activation of protein kinase C (PKC) by hyperglycemia. Recently, it has also been suggested that hyperglycemia-induced insulin resistance is in some way caused by increased flux of glucose through the glucosamine pathway.

Molecular mechanisms of insulin resistance

Insulin is a peptide hormone that binds to a transmembrane-spanning cell surface receptor (Figure 2). The insulin receptor is heterotetrameric in structure, containing two α - and two β -subunits. Insulin binds to the extracellular α -subunit, inducing a conformational change in the transmembrane β -subunit that derepresses intrinsic tyrosine kinase activity contained in the intracellular domain. The activated β -subunit tyrosine kinase activity first *trans*-phosphorylates the opposite β -subunit of the $\alpha_2\beta_2$ receptor complex. Once autophosphorylated, the insulin receptor is capable of phosphorylating intracellular proteins that propagate the insulin signal within the cell. Proteins of the insulin receptor substrate (IRS) family, the most important of these being IRS-1 and IRS-2, recognize and bind to phosphotyrosine motifs on the activated insulin receptor.

Figure 1 Factors contributing to insulin resistance and impaired insulin secretion include the ability for each of them to affect both themselves and each other through direct and indirect mechanisms.

Figure 2 Major signaling pathways of insulin action and abnormalities found in insulin resistance.

Once bound, the IRS proteins are themselves phosphorylated on multiple tyrosine residues by the activated insulin receptor. The IRS proteins do not have intrinsic enzymatic activity, but serve as docking sites to bring other proteins into proximity to the insulin receptor. A signaling cascade is initiated, as proteins recognize and bind to the phosphotyrosine motifs on either the insulin receptor or the IRS proteins. This results in their activation, often through their phosphorylation by the insulin receptor.

The downstream components of the insulin-signaling cascade include protein kinases and phosphatases, and lipid kinases. The two pathways that have been investigated in detail are the mitogen-activated protein (MAP) kinase and the phosphatidylinositol-3-OH (PI3) kinase pathways. Although the distinction is not absolute, activation of the MAP kinase pathway is most responsible for the actions of insulin related to cell growth, while activation of the PI3 kinase pathway is predominantly involved in the metabolic actions of insulin such as glucose uptake and glycogen synthesis. This is significant, because activation of the PI3 kinase pathway is markedly impaired in the insulin resistance of type 2 diabetes, while signaling through the MAP kinase pathway is much less impaired. This difference may contribute to the pathogenesis

of the long-term complications of insulin resistance and diabetes. A third pathway involves phosphorylation and activation of the Cbl proto-oncogene by the insulin receptor, which results in activation of the G protein TC10. Many of the pathways that are activated by the insulin receptor are also activated by other means, particularly activation of other growth factor receptors. Specificity of the insulin signal is felt to be due to the integration of the multiple pathways activated, as well as to compartmentalization of the components of the cascade. For example, both the PI3 kinase and Cbl/TC10 pathways may be necessary for insulin-stimulated glucose uptake into muscle and adipose cells, although the importance of the Cbl/TC10 pathway in insulin signaling remains uncertain.

Abnormalities of each of the components of the insulin-signaling cascade, from the insulin receptor at the beginning to the enzymes, transcription factors, and other effector proteins at the end, are potential candidates for contributing to the insulin resistance of type 2 diabetes. Indeed, a polymorphism near the IRS-1 gene was found to associate with insulin resistance and moderately increased risk for type 2 diabetes in Europeans. Otherwise, however, mutations or significant alterations in expression in these signaling components have been found only in isolated instances and have not been found to play a major role in the insulin resistance of type 2 diabetes. There have, however, been clearly identified abnormalities in insulin signaling that occur in the insulin resistance of type 2 diabetes (Figure 2). Notably, insulin-stimulated tyrosine phosphorylation of the insulin receptor and IRS proteins is decreased in tissues in insulin-resistant subjects. This is often associated with an increase in phosphorylation on specific serine and/or threonine residues in these proteins, which may inhibit the protein-protein interactions necessary for proper signaling. Potential mechanisms for this include serine-phosphorylation of the insulin receptor by PKC, and serine/threonine-phosphorylation of IRS-1 and IRS-2 by downstream mediators of insulin signaling (mammalian target of rapamycin (mTOR), mammalian target of rapamycin complex 1/p70 S6 kinase (mTORC1/S6K), and protein kinase C ζ (PKC ζ)) and other kinases. In particular, increases in, for example, free fatty acids, inflammatory cytokines, and reactive oxygen species (ROS) are found in obesity-activated serine phosphorylation of IRS-1 and IRS-2 proteins via glycogen synthase kinase (GSK), inhibitor of nuclear factor kappaB kinase (IKK β), and c-Jun N-terminal kinase (JNK).

In order to enter a cell, glucose requires specialized transporters to be present on the cell surface. GLUT4, the insulin-responsive glucose transporter, is sequestered in intracellular vesicles in the basal state. When muscle or adipose cells are stimulated by insulin, these vesicles translocate and fuse with the plasma membrane, and the increase in transporters at the cell surface results in increased glucose uptake. In the insulin resistance of obesity and type 2 diabetes, there is a decrease in the insulin-stimulated translocation of GLUT4. There may also be a decrease in the intrinsic activity of GLUT4 in insulin-resistant states. In adipocytes (but not muscle cells) there is significantly decreased expression of GLUT4 that contributes to the diminished insulin-stimulated glucose uptake. Although quantitatively adipose tissue contributes only a small fraction to glucose disposal compared to muscle, evidence from animal models with tissue-specific insulin resistance demonstrates that insulin resistance in one tissue can affect insulin sensitivity

in other tissues. Thus, insulin resistance in the adipocyte can cause insulin resistance in liver and muscle, most likely through secreted factors including free fatty acids, retinol-binding protein 4, and adipokines.

Insulin secretory defect

Insulin secretion and β -cell mass increase to compensate for states of insulin resistance such as obesity, pregnancy, or cortisol excess, so that fasting and meal-stimulated insulin levels are elevated even as glucose levels remain normal. When insulin secretion fails to fully compensate for the degree of insulin resistance, glucose levels rise, first to those of mild glucose intolerance (glucose levels above normal but below criteria for a diagnosis of diabetes), and then to those of diabetes. Insulin levels early in this progression are still elevated compared to individuals with normal insulin sensitivity, but are not elevated sufficient to maintain normal glucose control. With time, in most patients, the insulin secretory defect continues to worsen, including loss of β -cells, ultimately requiring exogenous insulin treatment to maintain control of blood glucose levels.

The development of impaired insulin secretion is likely due to both genetic and environmental factors. Indeed, variants at more than 20 genetic loci have recently been identified as playing a role in type 2 diabetes risk; of these, most appear to affect insulin secretion, but detailed mechanisms of action remain to be elucidated. Gene variants may also affect an individual's response to nongenetic factors. One factor contributing to the loss of β -cell function may be a persistent stimulus to oversecrete insulin caused by insulin resistance (Figure 1). This may be due in part to the effect of excessive secretion of islet amyloid polypeptide (IAPP), which is cosecreted with insulin; in the islets in the majority of patients with type 2 diabetes there is the accumulation of amyloid, containing IAPP. Another factor is the elevated free fatty acid level present in insulin resistance, which can contribute to the defective insulin secretion, just as it can contribute to insulin resistance. While short-term exposure to lipids increases insulin secretion, long-term exposure impairs β -cell function, and may be responsible for β -cell death by apoptosis. Similarly, prolonged exposure to increased glucose levels imposes a glucotoxicity on the β -cell; if glucose levels are normalized in a patient with diabetes, endogenous insulin secretion will improve. Over time, however, this glucotoxicity may lead to irreversible β -cell damage, perhaps through oxidative injury. Inflammatory cytokines such as IL-1 β also appear to induce β -cell apoptosis, which may be important in proinflammatory states such as obesity. Finally, insulin resistance of the β -cell may itself lead to impaired β -cell function, as demonstrated in mice carrying genetic defects of insulin signaling in β -cells.

Recent investigations have implicated endoplasmic reticulum (ER) stress and the unfolded protein response (UPR) in the pathogenesis of type 2 diabetes. The strongest evidence supports a role for the UPR in contributing to β -cell loss, although there are also data indicating that it can contribute to insulin resistance. The UPR is activated in cells when protein synthesis exceeds the capacity of the ER to properly fold them. The response includes a global decrease in protein translation, an increase in the degradation of misfolded proteins, and a specific increase in production of proteins that assist in the folding of proteins within the ER, such as chaperones. When

these steps fail to prevent the accumulation of misfolded proteins, apoptosis is triggered. The rate of proinsulin production can approach 1 million molecules per minute per cell, making it clear why β -cells are at risk of activation of the UPR. A clear demonstration that the UPR can contribute to β -cell loss is the monogenic disease Wolcott-Rallison syndrome, a rare disorder that includes insulin-deficient diabetes with an onset in infancy. It is caused by a mutation in the *EIF2AK3* gene, which encodes a protein (eukaryotic initiation factor 2 α (eIF2 α)) kinase 3, equivalent to rodent protein kinase RNA-like endoplasmic reticulum kinase (PERK)) that is central to the UPR.

Other Specific Types

Diabetes of types other than type 1 or type 2 make up a small percentage of the cases of diabetes. For a number of these, however, a single gene defect results in the disease, providing potential insight into what may be the underlying cause of the insulin resistance or insulin secretory defect in type 2 diabetes.

Genetic Defects of β -Cell Function

Maturity-Onset Diabetes of the Young

MODY (also known as monogenic diabetes of the young) refers to a group of diabetes types caused by mutations in single genes and having autosomal dominant inheritance. MODY patients have early-onset diabetes presenting in young adulthood (usually before the age of 25 years). In contrast to type 2 diabetes, obesity and insulin resistance are not a major feature of MODY; the diabetes in these cases is due to the defective insulin secretion. Clinical characteristics of the diabetes depend on the underlying mutation, and the severity of the untreated diabetes can vary from mild, sometimes unrecognized hyperglycemia with little risk of long-term microvascular diabetic complications, to severe hyperglycemia with a very high risk of microvascular complications.

MODY-causing mutations in six genes have been established from studies in multiple populations, and three additional MODY-causing mutations have been more recently identified, so far in specific populations. One form of MODY (MODY2) is caused by heterozygous mutations in the gene for glucokinase, which is expressed in highest levels in the pancreatic β -cell and in the liver. In the β -cell, glucokinase catalyzes the phosphorylation of glucose to generate glucose-6-phosphate, the first step in glucose metabolism. Because glucose metabolism is the stimulus for insulin release, glucokinase functions as the glucose sensor in the β -cell as it is rate limiting for glucose entry into the glycolytic pathway. Thus, glucokinase mutations lead to decreased glucose-stimulated insulin secretion. In the liver, glucokinase affects the storage of glucose as glycogen; this defect may contribute to the hyperglycemia in patients with glucokinase mutations.

Other genes that have been identified as having mutations that cause MODY are each transcription factors expressed in the pancreatic β -cell: hepatocyte nuclear factor (HNF)-4 α (MODY1); TCF1, which encodes HNF-1 α (MODY3); insulin promoter factor-1 (IPF1, also known as PDX-1; MODY4); TCF2, which encodes HNF-1 β (MODY5); neurogenic differentiation 1/ β -cell E-box transactivator 2 (NeuroD1/BETA2;

MODY6); and Kruppel-like factor 11 (KLF11; MODY7). Each of these genes is expressed in the β -cell and regulates expression of the insulin gene and genes for other factors involved in the regulation of insulin signaling; heterozygous mutations lead to β -cell dysfunction sufficient to cause diabetes. IPF-1, NeuroD1/BETA2, and paired box 4 (PAX-4; MODY9) are also involved in pancreatic development.

A syndrome of pancreatic exocrine insufficiency and β -cell dysfunction causing diabetes (MODY8) is caused by mutations in the gene for carboxy-ester lipase, expressed in the exocrine pancreas. The mechanism of action is unknown, and to date this appears to be a rare cause of MODY.

Neonatal Diabetes

Rarely, children may inherit a defect in insulin production which causes diabetes in infancy. Neonatal diabetes, usually present before 6–12 months of age, is non-immune-mediated and may be transient or permanent. Individuals who had transient neonatal diabetes are at increased risk of developing nonimmune type 1 diabetes at a later age. Mutations causing neonatal diabetes have been identified in genes involved in insulin production and secretion in β -cells (insulin, glucokinase, and components of a key potassium channel involved in insulin secretion: Kir6.2 and sulfonylurea receptor (SUR)), transcription factors expressed in the pancreas whose dysfunction causes pancreatic agenesis (IPF-1 and PTF1A) and genes operating through other mechanisms (*EIF2AK3*, *FOXP3*, and *GLIS-3*).

Some of the genes involved in MODY or neonatal diabetes can be associated with different forms of diabetes based on the severity of the genetic abnormality. In the case of the glucokinase and IPF-1 genes, a specific mutation causes MODY (when one copy of the gene is mutated) or neonatal diabetes (when both copies are mutated). In other cases, different mutations in the same gene are associated with neonatal diabetes, MODY, and/or type 2 diabetes (e.g., *HNF-1 β* , *HNF-4 α* , Kir6.2, insulin gene, and KLF11). For the case of the glucokinase gene, other mutations associate with fasting hyperglycemia but not diabetes. Some type 2 diabetes risk variants also impact gestational diabetes (see below). In addition to the above cases predisposing to forms of diabetes, other mutations in several of the above genes can cause syndromes of excessive insulin secretion and hypoglycemia.

Mitochondrial DNA Mutations

Mutations in the mitochondrial genome can cause diabetes mellitus, the most common involving the mitochondrial tRNA^{LEU(UUR)}. Due to the maternal origin of mitochondria, this type of diabetes is maternally inherited. The pancreatic β -cell is rich in mitochondria and has a high rate of oxidative metabolism; the mitochondrial mutations result in a β -cell defect that causes diabetes through deficient insulin secretion. This form of diabetes is frequently associated with neurosensory deafness.

While inherited mitochondrial genome mutations are rare as a cause of diabetes mellitus, they may provide insight into the worsening insulin secretory defect that occurs in type 2 diabetes. The mitochondrial genome consists only of coding sequences, and its repair mechanisms are poor so that it is

highly susceptible to mutation. With age, there is an increase in ROS generated in mitochondria, and this may be exacerbated in β -cells with a higher rate of oxidative metabolism due to exposure to elevated glucose levels. With a low expression of enzymes that defend against oxidative damage, β -cells are particularly sensitive to oxidative injury. The inherited mitochondrial genome mutations that cause diabetes demonstrate that these mutations can impair insulin secretion (though the exact mechanism is unknown), and it is possible that an accumulation of mitochondrial DNA mutations due to oxidative damage contributes to the β -cell dysfunction of type 2 diabetes.

Genetic Defects in Insulin Action

Insulin Receptor Mutations

Insulin resistance can be caused by mutations of the insulin receptor, although these are rare as a cause of diabetes. Most of the subjects identified with insulin resistance and insulin receptor mutations have mutations of both alleles. Some cases of mild insulin resistance have been described in which only one allele carries a mutation, acting as a dominant negative inhibitor of the wild-type allele, due to their combination within the heterotetrameric structure of the receptor. The severity of the phenotype with two mutant insulin receptor alleles can vary from insulin resistance with relatively normal glucose control (type A insulin resistance) to a more severe phenotype evident in infancy (Rabson–Mendenhall syndrome and Leprechaunism, which is usually fatal in infancy).

Secondary Diabetes Mellitus

A number of systemic disorders can cause marked insulin resistance, which can lead to secondary diabetes mellitus (although as for type 2 diabetes and as discussed above, there must be some defect in insulin secretion to prevent complete compensation for the insulin resistance by the β -cell). Excess growth hormone, as in acromegaly, excess glucocorticoid, as in Cushing's disease or exogenous glucocorticoid treatment, or excess catecholamines, as in pheochromocytoma, as well as other diseases such as uremia and hepatic cirrhosis can lead to secondary diabetes primarily through their effect on insulin sensitivity. Similarly, diabetes mellitus will occur if a disorder produces sufficient β -cell damage. Examples of this include pancreatitis, cystic fibrosis, pancreatectomy, and hemochromatosis; in addition, somatostatin-secreting tumors can inhibit insulin secretion sufficient to cause diabetes mellitus.

Rarely, patients with autoimmune disease have been identified where antibodies against the insulin receptor block signaling, leading to an insulin resistant form of diabetes referred to as type B insulin resistance.

Strikingly, just as the excess adipose tissue in obesity leads to insulin resistance, the deficiency of adipose tissue that is found in lipoatrophy/lipodystrophy also causes insulin resistance, often severe. Mice that are genetically engineered to have a paucity of adipose tissue are also markedly insulin resistant, confirming this association. The cause of insulin resistance in syndromes of adipose deficiency is likely due to intrahepatic and intramuscular accumulation of triglyceride, as well as a loss of normal secreted signals from adipocytes.

Gestational Diabetes

Glucose intolerance that is first identified during pregnancy is referred to as gestational diabetes. The importance of this classification is the significant maternal and fetal morbidity related to diabetes during pregnancy, warranting screening for diabetes mellitus in all pregnant women except those at low risk. In some cases gestational diabetes is merely the identification of glucose intolerance that was previously unrecognized until screening is performed during a pregnancy, or to the temporal development of diabetes (type 1 or type 2) during a pregnancy, perhaps accelerated by the pregnant state, but otherwise predestined to develop. In the majority of cases, however, glucose regulation returns to normal after the pregnancy. Pregnancy is characterized by progressively decreasing insulin sensitivity, due to the insulin antagonizing effects of increases in prolactin, human placental lactogen, estrogens, progesterone, and unbound cortisol levels. In the majority of pregnancies, this insulin resistance is compensated for by increased insulin secretion. However, in the 2–5% of pregnancies that develop gestational diabetes mellitus, there is an inadequate compensation. Thus, gestational diabetes represents the same or similar pathophysiologic abnormality of insulin sensitivity and insulin secretion that occurs in type 2 diabetes, perhaps revealed by the insulin resistance of pregnancy. Indeed, women who have had gestational diabetes are at a substantially increased risk for the future development of type 2 diabetes. A number of common gene variants have been found to increase the risk for both type 2 diabetes and gestational diabetes, supporting the hypothesis that some of the underlying pathophysiology is shared.

Metabolic Syndrome and Prediabetes

Insulin resistance often precedes the development of diabetes mellitus by many years. In addition, in some people, β -cell dysfunction does not develop, and insulin resistance exists indefinitely without progressing to diabetes. However, insulin resistance is not without significance of its own. The metabolic syndrome (also referred to as syndrome X) is an association of findings that frequently coexist, and includes insulin resistance, obesity (particularly abdominal/visceral rather than peripheral/subcutaneous), hypertension, and a specific form of dyslipidemia: hypertriglyceridemia and decreased high-density lipoprotein (HDL) cholesterol. These subjects are at risk of developing type 2 diabetes if they do not already have it, but more importantly, even in the absence of progression to diabetes, these individuals are at a markedly elevated risk for atherosclerotic vascular disease. The causality of obesity and insulin resistance in this syndrome is supported by the fact that lipid levels and hypertension may both be improved by decreasing insulin resistance through exercise and weight loss.

The diagnosis of diabetes mellitus is based on blood glucose levels that exceed defined levels, either in the fasting state or after a challenge with an ingested glucose load. The cutoffs are based mostly on levels that predict an increased risk for diabetic microvascular complications. Some individuals with insulin resistance will have glucose levels that do not meet criteria for the diagnosis of diabetes, but exceed levels considered normal. Some of these subjects with impaired fasting

glucose or impaired glucose tolerance will have glucose levels that revert to normal, or remain impaired over time. However, a large percentage will have progressive β -cell dysfunction (or worsening insulin resistance, or both) that results in progression to type 2 diabetes — ~40% in 5–10 years.

Complications

Acute

Ketoacidosis

DKA is the life-threatening acute metabolic decompensation in patients with diabetes mellitus. Because the development of DKA is suppressed by even modest insulin action, DKA is generally only a risk for patients with type 1 diabetes. The pathophysiology of DKA is one of acidosis, hyperosmolarity, and dehydration.

Decompensation toward DKA begins with a fall in insulin action, either due to an absolute decline in the insulin level, or due to antagonism of insulin action by cytokines and stress hormones, including catecholamines, cortisol, glucagon, and growth hormone. As insulin action becomes inadequate, serum glucose levels rise; the loss of insulin suppression of gluconeogenesis and glycogenolysis in the liver results in an increase in hepatic glucose output, and the loss of insulin stimulation of glucose uptake in muscle and adipose tissue results in accumulation of the excess glucose in the blood. The loss of insulin suppression results in unrestrained lipolysis in the adipocyte, releasing free fatty acids and glycerol. Increased protein breakdown in muscle releases amino acids. These metabolites are taken up by the hepatocytes, where the free fatty acids are metabolized to ketoacids (β -hydroxybutyrate and acetoacetic acid), and the glycerol and amino acids serve as substrates for accelerated gluconeogenesis.

The hyperglycemia and ketoacidosis are initially moderated by the loss of glucose and ketoacids in the urine. However, the glucosuria produces an osmotic diuresis, and the ketoacidosis produces an ileus leading to nausea and vomiting that impairs the ability of the patient to drink to maintain their hydration. As dehydration develops, then worsens, the glomerular filtration rate of the kidney falls, and less glucose and ketoacids can be excreted in the urine, resulting in dramatic accumulation of glucose and ketoacids in the blood. The evolving disease stimulates (further) release of stress hormones that antagonize any remaining insulin action, and further exacerbate the hyperglycemia. The acidosis and the hyperosmolarity caused by the extreme hyperglycemia decrease cerebral function and impair the patient's consciousness, further compromising the patient's ability to drink. Without intervention, death is inevitable.

Nonketotic hyperosmolar coma

Patients with type 2 diabetes are not at much risk of developing DKA. They will generally have sufficient insulin action to restrain lipolysis, limiting free fatty acid delivery to the liver and subsequent ketoacid production. However, decompensation similar to that of DKA, but without the excess ketoacid production, can occur in patients with type 2 diabetes. Nonketotic hyperosmolar coma in patients with type 2 diabetes generally occurs when another illness induces a stress response, and there is an impaired ability to maintain hydration with

oral fluids. As in DKA, the increase in stress hormones antagonizes insulin action, resulting in increased hepatic glucose production and decreased peripheral glucose utilization. The rising hyperglycemia produces a glucosuria-driven osmotic diuresis. Dehydration is a result of an inability of oral fluid intake to compensate for the osmotic diuresis. As in DKA, the dehydration impairs the renal excretion of glucose, allowing the glucose level to continue to rise. The dehydration and hyperosmolarity impair the patient's consciousness, and oral intake falls further. The final situation is one of marked hyperglycemia, hyperosmolarity, and dehydration. As in DKA, the mortality of nonketotic hyperosmolar coma is high.

Chronic

Patients with diabetes will occasionally have bothersome symptoms and are at risk of severe acute metabolic decompensation. Even if treatment is successful in avoiding these issues, diabetes can lead to long-term complications that develop over years. These complications can be categorized as microvascular, which are unique to patients with diabetes, and macrovascular, which are complications of atherosclerotic vascular disease that also occur in people without diabetes, but occur with higher frequency in those with diabetes. These complications are felt to be due to a failure of treatment to adequately normalize insulin and glucose levels, as well as to changes produced by insulin resistance in type 2 diabetes.

Macrovascular disease

As in individuals without diabetes, atherosclerotic changes in medium- and large-sized arteries that either partly or completely occlude the vessel lumen lead to morbidity and mortality due to impaired blood flow to the heart (angina and myocardial infarction), the brain (stroke), or the periphery (claudication and ischemic damage requiring amputation). These complications occur at 2–15 times greater frequency and develop at younger ages in patients with diabetes; over half of patients with type 2 diabetes die from cardiovascular disease. It is not fully clear how diabetes contributes to the risk of atherosclerotic vascular disease. The factors that have been implicated include lipid abnormalities, hyperglycemia, and increases in prothrombotic and proinflammatory factors. In addition, the coexistence of other atherosclerotic risk factors, especially hypertension, smoking, and obesity, also plays a role.

In patients with type 2 diabetes, the insulin resistance that is a part of the pathophysiology is associated with a specific pattern of lipid abnormality that increases the atherosclerotic risk: decreased HDL cholesterol concentration, and elevated triglyceride concentration in the serum. In addition, the inadequate insulin action in poorly controlled diabetes of any type leads to inadequate stimulation of lipoprotein lipase activity and to increased lipolysis and elevated free fatty acids. The free fatty acids that are not oxidized to ketones in the liver are re-esterified to triglycerides and secreted as very low density lipoproteins (VLDLs). Thus, poorly controlled diabetes can lead to atherosclerotic risk by increasing triglyceride and VLDL levels; hypertriglyceridemia can exacerbate the risk by depressing HDL levels. Hyperglycemia may contribute to disordered

serum lipids by reducing expression of the heparin sulfate proteoglycan perlecan on hepatocytes, leading to increased levels of the atherogenic cholesterol-enriched apolipoprotein B-containing remnant particles. Finally, glycated LDL is more susceptible to oxidation and is more atherogenic.

Endothelial dysfunction is central to the development of atherosclerosis, with decreased production of the vasodilating molecule nitric oxide and increased production of the pro-thrombotic factor plasminogen activator inhibitor-1 (PAI-1) – two factors implicated in this dysfunction. In diabetes, hyperglycemia inhibits nitric oxide production and increases production of PAI-1. Hyperglycemia may also contribute to macrovascular disease indirectly through microvascular damage to the nutrient blood vessels supplying the walls of the medium- and large-sized arteries.

Another aspect that is likely to play a role in the development of atherosclerosis in type 2 diabetes relates to the pathway-specific insulin resistance that is present. As noted previously, the insulin resistance of type 2 diabetes has less of an effect on the activation of the intracellular MAP kinase pathway than the pathway activating phosphatidylinositol-3-kinase. This may lead to increased activation of the MAP kinase pathway by insulin signaling, which also decreases nitric oxide production and increases PAI-1 production. In addition, as the MAP kinase pathway is a mitogenic pathway, the increased MAP kinase signaling can increase proliferation of the vascular smooth muscle cells, contributing to the atherosclerotic process.

Microvascular disease

The hyperglycemia of diabetes mellitus leads to damage to the microvascular circulation that results in tissue and organ damage, most notably in the retina, kidneys, and nerves. Due to these microvascular complications, diabetes mellitus is a leading cause of blindness, end-stage renal disease, and neuropathy. Increasing degrees of hyperglycemia are the main risk factor for microvascular complications, with the Diabetes Control and Complications Trial (for type 1 diabetes) and the United Kingdom Prospective Diabetes Study (for type 2) definitively demonstrating a decreased incidence of microvascular complications with treatments that lower the degree of hyperglycemia. Unfortunately, even the best of current therapies do not completely normalize blood glucose levels. Also, elevated triglycerides, decreased HDL, and elevated apolipoprotein C-III independently correlate with progression of microvascular disease, and treatment of diabetic dyslipidemia delays progression of diabetic nephropathy. The risk of microvascular complications increases with time, with the earliest evidence uncommon prior to a duration of hyperglycemia of 5 years; note, however, that except for typical type 1 diabetes, hyperglycemia may be present for years before the diagnosis of diabetes is made. Finally, as yet undefined genetic factors also play a role in the risk of microvascular disease.

Microvascular disease begins with abnormal blood flow and increased vascular permeability due to decreased activity of vasodilators, increased activity of vasoconstrictors, and overexpression of permeability factors. Irreversible increases in vascular permeability occur with alterations in the extracellular matrix. Ultimately, there is cell loss, capillary occlusion from deposition of extravasated plasma proteins, and the overproduction of extracellular matrix. Microvascular disease affects the glomerulus

in the kidney, with the earliest evidence being leakage of albumin into the urine and progressing to loss of glomerular function. Damage to retinal capillaries causes hypoxic-ischemia, edema, new vessel formation, and hemorrhage. It is the development of new vessels, referred to as proliferative retinopathy, that can lead to retinal detachment, vitreous hemorrhage, and loss of sight. Diabetic neuropathy includes degeneration of motor, sensory, and autonomic nerves.

While it is clear that hyperglycemia leads to microvascular disease, the precise mechanism for this has not been completely demonstrated. However, five pathologic processes triggered by hyperglycemia have been identified and proposed as causative mechanisms: increases in the polyol and hexosamine pathways, production of advanced glycation end-products (AGEs), oxidative stress, and activation of PKC. *In vivo* studies with inhibitors, either in animal models or in human subjects, have supported a role for each of these pathways (except the recently implicated hexosamine pathway) in microvascular pathology. The relative contribution of each of these proposed mechanisms likely varies across cell types.

Elevated triglycerides, decreased HDL, and elevated apolipoprotein C-III also independently correlate with progression of microvascular disease, and treatment of diabetic dyslipidemia delays progression of diabetic nephropathy.

Polyol pathway

Hyperglycemia drives an increased intracellular generation of sorbitol through the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reduction of glucose by aldose reductase. Increased production of sorbitol could alter cellular functions in a number of ways, including increasing intracellular osmotic stress, decreasing myoinositol and taurine (as compensation for the increase in sorbitol in order to prevent or mitigate an increase in osmolarity), or through an increased NADH/NAD⁺ ratio (due to NAD⁺-dependent oxidation of sorbitol to fructose). However, the most likely mechanism for cellular dysfunction caused by increased flux through the polyol pathway is due to the consumption of NADPH. This leads to a lack of NADPH available to regenerate reduced glutathione, limiting the ability of the cell to protect itself against oxidative stress.

Hexosamine pathway

The hexosamine pathway generates uridine diphosphate (UDP)-*N*-acetylglucosamine (GlcNAc) from glucose to provide substrate for proteoglycan synthesis and for O-linked glycosylation of certain proteins. The activity or function of many proteins, including transcription factors, can be modified by O-linked glycosylation, often in concert with reciprocal modification by phosphorylation. With hyperglycemia, some of the excess glucose is shunted into the hexosamine pathway. As noted previously, increased flux through this pathway may play a role in insulin resistance. In addition, increased generation of UDP-GlcNAc could alter gene expression and cellular function through excess protein glycosylation, contributing to the pathogenesis of microvascular disease.

Advanced glycation end-products

Glucose will react with free amino groups on proteins in a nonenzymatic reaction to form glycated proteins. This reaction

starts with the formation of a Schiff base (aldamine), which then undergoes an internal Amadori rearrangement. The formation of the Schiff base is rapid and reversible, while the Amadori rearrangement is much slower and results in a more stable ketoamine. This process occurs at a rate proportional to the prevailing glucose level that a given protein is exposed to. The glycation of hemoglobin is used clinically to estimate the average blood sugar in patients with diabetes, as the percent of hemoglobin in the glycated A_{1c} form (HbA_{1c}) is proportional to the average glucose level present over ~3 months prior to testing (roughly the red blood cell life span).

Proteins modified irreversibly through nonenzymatic reaction with glucose or glucose-derived compounds are referred to as AGEs. Most AGEs are not formed through the reaction of proteins directly with glucose but rather with three reactive dicarbonyl compounds that are produced intracellularly from glucose: glyoxal (an auto-oxidation product of glucose), 3-deoxyglucosone (formed from decomposition of the Amadori product of glucose), and methylglyoxal (from fragmentation of glyceraldehyde-3-phosphate and dihydroxyacetone phosphate generated from glycolysis). The reactive dicarbonyls interact with the amino groups of proteins, and can introduce both intra- and intermolecular cross-links. AGE formation may lead to microvascular damage through alteration of the function of both intracellular and extracellular proteins modified in this way. In particular, the modification of extracellular matrix proteins by this process is likely to contribute to abnormal vascular permeability and elasticity. In addition, however, AGEs formed from plasma proteins bind to and activate specific AGE receptors on endothelial cells, mesangial cells, and macrophages (one such receptor is RAGE, a member of the immunoglobulin superfamily). Activation of AGE receptors induces production of cytokines, growth factors, procoagulatory factors, and ROS. Induction of vascular endothelial growth factor (VEGF) by AGE receptor activation most likely contributes to the increased permeability of capillary walls present in diabetes.

Activation of PKC

Hyperglycemia increases intracellular diacylglycerol (DAG) levels, which is an activator of many of the PKC isoforms. Hyperglycemia may also activate PKC isoforms indirectly by increasing ROS from activation of AGE receptors and from increased activity of the polyol pathway. As discussed above, activation of PKC may play a role in hyperglycemia-induced insulin resistance. Mechanisms through which activation of PKC may be involved in the development of microvascular disease include: inhibiting production of the vasodilator nitric oxide; increasing activity of the vasoconstrictor endothelin-1; increasing expression of VEGF, leading to increased cell permeability; and contributing to the accumulation of extracellular matrix protein by inducing expression of transforming growth factor (TGF)- β 1, fibronectin, and type IV collagen.

Oxidative stress

The increased metabolism of glucose in the presence of hyperglycemia increases the delivery of electron donors from the tricarboxylic acid cycle to mitochondria. This can lead to an increase of the proton gradient across the inner mitochondrial

membrane, inhibiting the electron transport chain and increasing production of superoxide and other ROS. Oxidative stress can directly contribute to the development of microvascular complications by stimulating signal transduction pathways resulting in altered cellular functions and gene expressions. In addition, ROS can react with and damage DNA, proteins, and lipids. ROS can trigger mitochondria to release cytochrome *c*, triggering apoptosis. In addition to these direct actions of ROS, oxidative stress can activate the other potential microvascular pathogenic pathways. Because superoxide inhibits the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase, precursors can accumulate and be diverted into the polyol pathway (glucose), the hexosamine pathway (fructose-6-phosphate), production of DAG (glyceraldehyde-3-phosphate), which activates PKC isoforms, and production of the reactive dicarbonyl methylglyoxal (glyceraldehyde-3-phosphate), which produces AGEs.

Diabetes Treatment Medications – Mechanisms of Action

Patients with diabetes of any type can be treated with insulin to overcome the relative or absolute insulin deficiency. For patients with type 1 diabetes, the loss of the ability to produce endogenous insulin because of the loss of pancreatic β -cells makes insulin a required treatment. Similarly, in many patients with type 2 diabetes, the β -cell dysfunction will progress to a degree that insulin treatment is necessary to maintain glycemic control. However, for many patients with type 2 diabetes, a number of treatments may be effective in lowering the degree of hyperglycemia instead of or in addition to insulin.

Weight Loss and Exercise

For the majority of patients with type 2 diabetes, obesity is a significant contributor to the insulin resistance that underlies their disease. Therefore, in many cases, if the patient is able to lose weight, insulin sensitivity will improve sufficiently to return metabolic control to normal or near normal. In many cases, only modest weight loss can be effective. A sedentary lifestyle also leads to decreased insulin sensitivity. Therefore, exercise to improve fitness can also improve insulin sensitivity sufficient to ameliorate the diabetic state, an effect that can occur in the absence of weight loss. Key mechanisms for this improved insulin sensitivity are the exercise-induced stimulation of AMP-activated kinase (AMP kinase) and PI3 kinase activities. One of the effects of the activation of AMP kinase is to directly increase GLUT4 translocation to the plasma membrane, increasing cellular glucose uptake. Prolonged exercise training also increases expression of both AMP kinase and GLUT4.

Exercise also induces the upregulation of factors such as peroxisome proliferator-activated receptor γ coactivator 1 α (PGC-1 α), peroxisome proliferator-activated receptor- γ (PPAR- γ), and nuclear respiratory factor 1 (NRF1), which induce an increased synthesis of new mitochondria. This, along with the effect of AMP kinase activation on lipid metabolism, results in increased fatty acid oxidation which contributes to the improved insulin sensitivity.

Insulin Secretagogues

Sulfonylureas and meglitinide analogs lower blood sugar levels by stimulating endogenous insulin secretion. They act by binding to the SUR – one component of the β -cell potassium channel, the other being Kir6.2. Binding of these agents to SUR results in closure of the potassium channel, mimicking the effect of a glucose-driven increase in the cellular ATP/ADP ratio (ATP, adenosine triphosphate; ADP, adenosine diphosphate), and setting in motion the intracellular signal for exocytosis of insulin. Unfortunately, due to the worsening β -cell dysfunction and β -cell loss that occurs in most patients with type 2 diabetes, insulin secretagogues often become ineffective over time.

Metformin

Metformin is a biguanide compound that works by increasing insulin sensitivity in diabetic patients. Its main effect is on the liver, to decrease excess hepatic glucose production. The underlying mechanism for metformin's action has not been fully determined. However, it appears to function by activating AMP-activated protein kinase (AMPK). By activating AMPK, the hepatocyte shifts from lipogenesis to fatty acid oxidation. This reduces hepatic triglyceride content, which has been implicated in the cause of insulin resistance. Activation of AMPK may increase insulin sensitivity by interrupting the S6K-activated serine/threonine-phosphorylation of IRS protein, increasing their efficiency in insulin signaling. How metformin activates AMP kinase is uncertain, but may involve inhibition of the mitochondrial electron transport chain.

Thiazolidinediones

Thiazolidinediones (TZDs) are a second class of insulin-sensitizing drugs. In contrast to metformin, however, their primary action is to increase peripheral insulin sensitivity, thereby increasing glucose uptake into fat and muscle. TZDs are ligands for PPAR- γ , which is expressed in high levels only in adipose tissue, although low levels of expression are seen in other tissues, including in muscle, liver, and pancreatic β -cells. PPAR- γ is a transcription factor that alters gene expression in a ligand-dependent manner. The importance of PPAR- γ in the pathophysiology of diabetes is highlighted by the fact that a common amino acid polymorphism in the PPAR γ gene (proline instead of alanine at codon 12, occurring in both chromosomes in about 75% of Caucasians) confers decreased insulin sensitivity and insulin clearance and greater risk of type 2 diabetes. TZDs most likely exert their effect by altering PPAR- γ -dependent gene expression in adipocytes, which leads to improved insulin action in muscle and liver. However, TZDs have also been shown to stimulate AMPK in liver, muscle, and adipocytes cell culture systems. In addition, other mouse models suggest that PPAR- γ signaling in the pancreas may influence insulin secretion.

α -Glucosidase Inhibitors

Acarbose and miglitol inhibit the intestinal enzyme α -glucosidase. Given with meals, this delays carbohydrate absorption, leading to a requirement for a lower maximal insulin level to dispose of the

absorbed carbohydrate. These drugs do not significantly affect fasting glucose levels, and so are generally ineffective as single agent therapy. However, there is accumulating information demonstrating the importance of controlling postprandial hyperglycemia to minimize long-term diabetic complications.

Incretin Hormones

Glucagon-like peptide-1 (GLP-1) agonists and dipeptidyl-peptidase-4 (DPP-4) inhibitors act in different ways to activate insulin secretion via the incretin pathway. The incretin pathway is rapidly activated when ingestion of oral carbohydrate stimulates production of gastric inhibitory peptide (GIP) and GLP-1, mainly by L-cells in the small intestine. GIP and GLP-1 are rapidly degraded by peptidases, primarily DPP-4, and cleared by the kidneys. These hormones, termed incretins, bind receptors on pancreatic α - and β -cells to stimulate insulin and decrease glucagon secretion, and also inhibit gastric emptying and decrease appetite. Incretins have also been shown to decrease β -cell apoptosis *in vitro* and promote β -cell proliferation in rodent models. Medications which mimic the action of GLP-1 (e.g., exenatide) or prolong the action of endogenous GLP-1 by inhibiting DPP-4 (e.g., sitagliptin) are now in clinical use and have been shown to be effective at improving blood glucose as first- or second-line agents in the treatment of type 2 diabetes. Whether the antiapoptotic effects seen in model systems are clinically significant in humans is under investigation.

Bromocriptine

Bromocriptine is a sympatholytic dopamine D2 receptor agonist. It has been demonstrated to produce improved glycemic control in patients with type 2 diabetes. The mechanism of this action is unknown, but it is presumed to act centrally to modulate neuronal signals from the central nervous system that regulate metabolism.

Treatments Directed at Diabetic Complications

The above medications are primarily used to improve hyperglycemia and insulin sensitivity in diabetes patients. It is also important to treat other risk factors that contribute to diabetes complications, particularly the macrovascular complications. Thus, treatment is directed at dyslipidemia and hypertension, important risk factors for atherosclerotic vascular disease. Inhibitors of hydroxymethylglutaryl-coenzyme A reductase, statins, decrease cholesterol biosynthesis and reduce the risk of cardiovascular disease. These agents may also act by reducing inflammation and oxidative stress in the vasculature, possibly partly via activation of AMPK. A number of other lipid lowering agents are effective. Of note, fibric acid derivatives

may be more effective in hyperlipidemic diabetic patients, and colesvelam (which acts by increasing cholesterol excretion in the form of bile acids) may also reduce hyperglycemia in diabetic patients.

An increase in the urinary loss of albumin is an early indicator of diabetic renal disease. Treatment of patients who have such microalbuminuria with angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) decreases the rate of progression to more significant renal impairment in such patients. Treatment of hypertension is undertaken to reduce the risk of macrovascular complications; because of their role in mitigating progression of diabetic nephropathy, ACE inhibitors and ARBs are often selected as the initial treatment for hypertension.

Glossary

Diacylglycerol (DAG) A lipid composed of a glycerol backbone with fatty acids attached by ester bonds to its first (*sn*-1) and second (*sn*-2) carbons.

Fatty acid Monobasic acids containing long hydrocarbon chains that can be either saturated (no double bonds) or unsaturated (one or more double bonds).

Phosphatidic acid (PA) DAG with a phosphate group attached to the third (*sn*-3) carbon of the glycerol backbone.

Phosphatidylinositol PA with an inositol group attached to the phosphate.

Phospholipid The major structural lipids of most cellular membranes. They contain one or more phosphate groups and, if derived from glycerol, are known as 'phosphoglycerides'.

Diacylglycerol (DAG) is an important lipid that is both an intermediate in lipid biosynthetic pathways and can also initiate specific intracellular signaling events. The majority of signaling DAG is generated by hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP₂) by the enzyme phospholipase C (PLC), but DAG can also be generated when phosphatidic acid phosphatases (PAPs) remove the phosphate head group from phosphatidic acid (PA) (Figure 1). DAG activates protein kinase C (PKC) isoforms, binds to and activates the RasGRP nucleotide exchange factors, and recruits the chimaerins, which are Rac guanosine triphosphatase (GTPase)-activating proteins (GAPs), to membranes. Because DAG can modulate a plethora of signaling events, it is crucial that intracellular DAG levels be tightly regulated. Though DAG can be metabolized in various ways, under most circumstances its major route for metabolism is by its phosphorylation, a reaction that is catalyzed by the diacylglycerol kinases (DGKs).

The DAG Kinases

Ten mammalian DGK isoforms have been identified (Figure 2). The heterogeneity of the gene family is similar to the PKC and PLC families, suggesting that the DGKs are not simply lipid biosynthetic enzymes, but that they also have signaling roles, because enzymes involved in biosynthetic pathways usually do not have extended families. One or only a few DGK isoforms have been identified in organisms such as *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Arabidopsis thaliana*. Single-celled organisms such as yeast and bacteria also have DGKs, and a multi-substrate lipid kinase that can phosphorylate DAG also exists in vertebrates, but these enzymes are not similar to mammalian DGKs and they will not be discussed here.

DGK isoforms are categorized based on common structural motifs. All DGK isoforms have a catalytic domain composed of catalytic and accessory motifs that is necessary for kinase activity. In most cases, the catalytic domain is a single motif, but DGKs δ , η , and κ have bipartite catalytic domains. All DGKs have at least two cysteine-rich regions homologous to the C1A and C1B motifs of PKCs. In theory, these domains may bind

DAG, perhaps localizing DGKs to where DAG accumulates. However, no DGK C1 domain has so far been conclusively shown to bind DAG. Structural predictions suggest that most DGK C1 domains may not bind DAG, and most DGKs tested are unable to bind long-lived DAG-like analogs. Houssa and van Blitterswijk noted that in DGKs, the C1 domain closest to the catalytic domain is highly conserved, including an extended motif of 15 amino acids not present in other C1 domains. Conserved residues in this extended motif have been shown to be crucial for DAG kinase activity. Together, these data suggest that DGK C1 domains are structurally different from C1 domains in other proteins and that the different C1 domains of a single DGK isoform may have unique functions. Distinct functions of individual C1 domains remain to be definitively demonstrated.

In addition to the C1 and catalytic domains, other regulatory domains are used to group the DGKs into five subfamilies. Type I DGKs have calcium-binding EF hand motifs and have been shown to be more active in the presence of calcium. Type II DGKs have a pleckstrin homology (PH) domain at their amino termini. This domain in DGK δ has been shown to bind weakly and nonselectively to phosphatidylinositols (PIs). DGKs δ and η also have sterile alpha motifs (SAM domains) at their C-termini that can modulate their cellular localization or act as protein–protein interaction sites. DGK ϵ , a type III enzyme, has an unusual specificity toward acyl chains of DAG, strongly preferring a specific fatty acid – arachidonate – at the *sn*-2 position. This preference suggests that DGK ϵ may be a component of the biochemical pathway that accounts for the enrichment of PIs with arachidonate. Type IV DGKs have a MARCKS phosphorylation domain and, at their C-termini, four ankyrin repeats. The type V enzyme, DGK θ , has three C1 domains and a PH domain.

Regulation of DGK Activity

Activation of the DGKs is complex and unique for each DGK isotype. In most cases, DGKs must translocate to a membrane compartment to access DAG. In addition, their activity can be

Figure 1 (a) Different enzymatic pathways can produce diacylglycerol (DAG) and phosphatidic acid (PA). Phospholipase C (PLC) enzymes generate DAG that can be phosphorylated by DGKs to produce PA. In another pathway, phospholipase D (PLD) hydrolyzes phosphatidylcholine (PC) – or phosphatidylethanolamine – making PA that can be further hydrolyzed by phosphatidic acid phosphatases (PAPs) to generate DAG. To date, there is little definitive evidence to suggest that the diacylglycerol kinase (DGK) and PAP reactions are coupled. Both DAG and PA can act as signaling lipids and are also intermediates in lipid biosynthetic pathways. (b) DAG and PA have the same general structure but contain different functional groups attached to the third (*sn*-3) carbon. Depending on their molecular structure, the fatty acyl groups confer different signaling properties to the DAG or PA.

modified by appropriate cofactors, and several DAG kinases are also regulated by posttranslational modifications. Finally, tissue-specific alternative splicing of DGKs β , γ , δ , ζ , ι , η , and possibly other isoforms allows additional opportunities for regulation. This complexity permits tissue- or cell-specific regulation of each DGK isotype, depending on the availability of cofactors and the type of stimulus that the cell receives.

DGK ζ is an example of the contextually dependent differential regulation of DGKs. DGK ζ translocates to at least two different membrane compartments in T lymphocytes depending upon the agonist used to activate the cells: from the cytosol to a perinuclear region in T cells stimulated with IL-2, and to the plasma membrane upon activation of the T-cell antigen receptor. Once at a membrane compartment, the DAG kinase activity of DGK ζ can be modified by the availability of several cofactors. Calcium is known to bind to EF hand structures and stimulates DGK ζ activity *in vitro*. Lipids also modify its activity: phosphatidylserine and sphingosine activate DGK ζ *in vitro* and likely *in vivo* as well. Finally, DGK ζ can be phosphorylated by several protein kinases, including some PKC isoforms and Src kinase, which may enhance its DAG kinase activity.

Like DGK ζ , other DGK isoforms appear to be sensitively regulated. For example, type II DGKs have a PH domain that may help localize these DGKs, modify their activity, or allow binding to other proteins. The PH domain of the type II

DGK δ binds PIs but its DAG kinase activity is not affected by these lipids. By contrast, the activity of DGK types III and IV can be modified by PIs and by phosphatidylserine, sometimes in opposing ways. For example, the type III enzyme, DGK ϵ , is inhibited by, whereas type IV DGKs are activated by, phosphatidylserine. Type IV DGKs are strongly regulated by subcellular translocation. These enzymes have a nuclear localization signal that is regulated by PKC phosphorylation, and there is evidence that the syntrophin family of scaffolding proteins further regulates their subcellular location by anchoring them in the cytoplasm. Finally, DGK θ , a type V DGK, can be regulated through its association with active RhoA, which abolishes its DAG kinase activity, while DGK ζ binds retinoblastoma family proteins, which stimulate its DAG kinase activity. Thus, depending on the context of activation, the availability of cofactors and binding partners, and the activation state of protein kinases, DGKs can be differentially regulated.

Activity of DGKs is Compartmentalized

Evidence suggests that DGK activity is restricted to the area of localized DAG pools generated after activation of receptors. This concept was initially tested in 1994 by Van der Bend et al., who detected DGK activity in cells following receptor activation but could not detect significant DAG kinase activity after treating the cells with exogenous PLC, which caused global, nonspecific DAG generation. Their data suggest that DGKs are active only in spatially restricted compartments following physiologic generation of DAG.

We are only beginning to understand the complexities of spatially restricted DGK function. Several DGKs localize to the cytoskeleton, where they may participate in regulating cytoskeleton dynamics. Houssa et al. showed that RhoA associates with DGK θ – but only when RhoA is in its active form – and that this interaction abolished DGK activity. RhoA appears to bind the catalytic domain of DGK θ , which probably physically impairs DAG kinase activity. Investigators have also noted that DGK activity associates with a complex of proteins including PI5K, Rac, Rho, Cdc42, and Rho-GDI, all of which regulate cytoskeleton dynamics. Evidence suggests that this might be DGK ζ , which helps promote Rac activation. Consistent with this possibility, DGK ζ localizes at the leading edge and cell extensions of glioblastoma cells and can disrupt cell spreading when overexpressed. We have also found in unpublished studies that other DGK isoforms co-immunoprecipitate with Rho family proteins when overexpressed in cells. The physiologic significance of these interactions is not clear, though, together, these data suggest that DGKs likely have a role in regulating the cytoskeleton.

In the nucleus, a distinct nuclear PI cycle is regulated separately from its plasma membrane/cytosolic counterpart. The function of DAG produced in the nucleus has received little attention, but data clearly indicate that, in most cases, it acts to promote cell growth independently of plasma membrane DAG. For example, some growth factors (e.g., IGF-1) can stimulate a pulse of nuclear DAG without causing a measurable change in extranuclear DAG, and several groups have demonstrated that nuclear DAG fluctuates independently of

Figure 2 The mammalian DGK and PAP families. Based on structural motifs, the 10 mammalian DGKs are divided into five subtypes. Alternative splicing of some DGK isoforms generates even more structural diversity. Many of the DGKs contain other unique structural domains that are not shown. The PAP family is a smaller family of enzymes that have two motifs in common: the N-terminal NLIP domain is of unclear significance while the C-terminal haloacid dehalogenase (HAD)-like domain with a DIDGT motif is required for their activity.

extranuclear DAG during the cell cycle. Nuclear DAG was shown to peak shortly before S phase, suggesting that it may participate in the G1/S transition. Supporting this conclusion and emphasizing the importance of DAG signaling in the cell cycle, we demonstrated that when a nuclear DGK was over-expressed, cells accumulated at the G0/G1 transition, presumably because the kinase attenuated the nuclear DAG concentration. Within the nucleus, DAG signaling, like its extranuclear counterpart, appears to be compartmentalized. For example, in 1999 D'Santos et al. demonstrated independently fluctuating pools of nuclear DAG with distinct fatty acid compositions, strongly suggesting the existence of multiple, differentially regulated pools of nuclear DAG.

DGKs are present in nuclei and appear to have prominent and specific roles there. DGKs α , ζ , and ι translocate to the nucleus, while a fraction of DGK θ is localized there constitutively. Different DGK subtypes are confined to specific, separate compartments within the nucleus, suggesting specificity in their nuclear roles. For example, DGK α associates with the nuclear envelope, while DGK θ and DGK ζ are found in discrete regions within the body of the nucleus. Evidence suggests that DGKs likely affect nuclear signaling either by terminating DAG signals or by generating PA. For example, nuclear DGK ζ inhibits progression from G1 to S phase of the cell cycle, likely by metabolizing DAG. Conversely, in T lymphocytes, PA generated by nuclear DGK α appears to be necessary for IL-2-mediated progression to S phase of the cell cycle. Thus, DGK α and DGK ζ appear to have opposing roles in the nucleus, reflecting the complexity of lipid signaling and DGK activity there.

Coupling of DGKs with Other Signaling Proteins

Recent evidence suggests that in addition to acting locally at sites of DAG pools, DGKs can specifically associate with and regulate signaling proteins that are activated by either DAG or PA. For example, DGK ζ associates with and inhibits RasGRP1, a guanine nucleotide-exchange factor for Ras that requires DAG to function. This regulation may be selective: five other DGK isoforms did not significantly inhibit RasGRP1 activity. In *C. elegans*, Nurrish et al. found that *dgc-1*, an ortholog of human DGK θ , regulates DAG signaling that is necessary for acetylcholine release. Combined, these data demonstrate that DGK activity is not only targeted at sites of DAG production, but also specifically directed toward a subset of DAG-activated proteins.

DGK Gene Deletion Studies in Mice

In an effort to understand their function, the genes encoding several DGK isoforms have been deleted in mice. These studies have revealed that several DGKs modulate signaling events downstream of plasma membrane receptors. For example, DGKs α and ζ suppress immune cell activation through the T-cell receptor while DGK δ is required for proper EGFR signaling. DGKs ι and ζ modulate Ras signaling by virtue of their ability to bind and regulate RasGRP exchange factors. Finally, DGK ϵ was found to be necessary for the maintenance of several signaling lipids in neuronal cells, and deletion of DGK ϵ protected mice from induced seizures. Collectively, these studies

underscore the importance of DGKs in lipid signaling events and demonstrate the diversity of their functions.

PA as a Signal

The DGK reaction is of special interest because it removes one signaling molecule, DAG, while generating another, PA. PA can stimulate DNA synthesis and is potentially mitogenic. It modulates the activity of several enzymes, including PI 5-kinases (PI5Ks), PAK1, Ras-GAP, and PKC ζ , and it has a prominent role in vesicle trafficking. At the plasma membrane, PA also helps recruit Raf and Son of sevenless (Sos). Although phospholipase D (PLD) generates the bulk of signaling PA (Figure 1), DGKs likely also contribute to its intracellular concentration.

The PA species generated by DGK and PLD reactions are distinct from each other by virtue of their initial substrates. Phosphatidylcholine, which is largely composed of saturated and mono-unsaturated fatty acids is the predominant substrate of PLD, while PA produced by DGKs is derived from DAG that is enriched in polyunsaturated fatty acids, particularly arachidonate. There is good evidence that each PA species – saturated and unsaturated – can differentially activate targets. For example, saturated PA species induce mitogen-activated protein kinase (MAPK) activation to a greater extent than unsaturated PAs; Flores and colleagues presented evidence that the PA produced by DGK α was necessary for stimulated T lymphocytes to progress to S phase of the cell cycle. Abramovici et al. recently demonstrated that DGK ζ generated PA to activate PAK1 that then initiated events to alter actin dynamics. Thus, DGKs can influence signaling events either by metabolizing DAG or by generating PA.

PA Conversion to DAG by PA Phosphatases

Just as PA can be generated by more than one enzymatic pathway, DAG is also the product of several enzymatic reactions. The PLC reaction is generally thought to be the major route to generate signaling DAG, but some lipid phosphatases can also produce DAG by dephosphorylating PA (Figure 1). These phosphatases fall into two groups. One group is composed of integral membrane proteins called 'lipid phosphate phosphatases (LPPs)', which are promiscuous and hydrolyze a diverse array of lipids that include PA, lysophosphatidic acid, sphingosine-1-phosphate, and ceramide-1-phosphate. The other group of enzymes is called 'PAPs'. These enzymes have specificity for PA and will be the focus of this section.

PA Phosphatase Enzymes

PAP activity in cellular lysates was originally identified in the 1950s, but the enzymes were not cloned until 2006, when the yeast protein encoded by the *PAH1* gene was shown to have PAP activity. Pah1p, the protein product of the *PAH1* gene, has a predicted molecular weight of 95 kDa and contains a haloacid dehalogenase (HAD)-like domain with a DIDGT motif that is crucial for phosphatase activity. There is also an

N-terminal NLIP domain of unknown significance (Figure 2). Based on sequence homology to Pah1p, a group of mammalian enzymes called 'lipins' were subsequently recognized to have PAP activity, which is now believed to be their primary enzymatic function. There are three known mammalian lipins – lipin-1, -2, and -3 – and alternative splicing yields two lipin-1 products called lipin-1A and lipin-1B. Lipin and Pah1p orthologs are now recognized in most vertebrates and invertebrates, and all of these enzymes strictly require Mg²⁺ for activity. In humans, the lipin enzymes are expressed in numerous tissues, with lipins-1 and -2 being predominantly expressed in adipose tissue.

Physiologic Roles of PA Phosphatases

Given the central role of the PAP reaction in the biosynthesis of many cellular lipid components, it is not surprising that mutant yeast lacking PAP activity accumulate PA and have altered levels of numerous lipids including DAG and triacylglycerol. These lipid abnormalities verified that PA phosphatases are crucial for proper lipid biosynthesis. Prior to the identification of Pah1p as a PA phosphatase, *Lpin1* (the gene encoding lipin-1) was identified as the mutated gene in fatty liver dystrophy (*fld*) mice. The *fld* mice develop numerous abnormalities including fatty liver, insulin resistance, lipodystrophy, and susceptibility to atherosclerosis. These abnormalities indicate that lipin-1, like its ortholog in yeast, has a central role in lipid biosynthesis. Additional studies have demonstrated that lipin-2 also has an important function in hepatic lipid homeostasis, while lipin-3 has not been studied as extensively.

In addition to their roles in lipid biosynthetic pathways, it is possible that PA phosphatases might also function in lipid signaling pathways. Supporting this possibility, there are several reports demonstrating agonist-induced phosphorylation of PA phosphatases or translocation of Mg²⁺-dependent PA phosphatase activity. Specifically, it has been postulated that PA phosphatases might generate DAG from PA that could then activate PKCs and other proteins. Indeed, DAG levels fall in the setting of PA phosphatase deficiency. But there is a distinction between the DAG that is an intermediate in lipid biosynthetic pathways and the DAG that acts as a signaling lipid. The lipid abnormalities in PA-phosphatase-deficient yeast and mice suggest that PA phosphatases are predominantly active in lipid biosynthetic pathways. So far, there is little published work supporting that DAG derived from the PA phosphatase reaction can act as a signaling lipid. Most data suggest that PA phosphatase activity is coupled to PLD activity, which by virtue of its substrates, predominantly generates PA with saturated fatty acids. As such, DAG that is generated by sequential PLD and PAP activity would be composed of predominantly saturated fatty acids. But evidence suggests that DAG composed of saturated fatty acids has weak signaling properties compared to unsaturated DAG. So based on present data, PAPs might generate DAG, but because of its fatty acid components, this DAG is not thought to initiate signaling. Instead, the PAP reaction probably functions to terminate PA signals that were initiated by PLD. It is also possible that PAP activity could couple with DGK activity to regenerate unsaturated DAG that

might initiate signaling, but no one has demonstrated that this cycle exists. Thus, PAPs theoretically could contribute to DAG signaling but evidence is lacking that they do so. However, this issue needs to be explored more definitively. Instead, it is more likely that PAPs predominantly function in lipid biosynthetic pathways or serve to terminate PA signaling when coupled with PLDs.

Conclusions

As evidence accumulates, it is apparent that the structural diversity of DGK isoforms mirrors the range of functions and sites of action of these enzymes. Further studies of the regulation of lipid signaling should reveal additional roles for DGKs and more precise information about their regulation. PAPs are a family of enzymes that have been known to exist for decades but were only recently cloned. They are a less diverse family of enzymes but have crucial functions in lipid biosynthetic pathways. Their role in lipid signaling is less clear, but PAPs probably terminate PA signals generated by the PLD reaction. Although it is possible that PAPs can contribute to DAG signaling, there is little definitive evidence at this point to demonstrate that they do.

Glossary

Bacterial periplasm A specialized compartment in between the inner and outer membrane of bacteria. Disulfide formation occurs in this compartment.

Disulfide bond A covalent bond between two sulfhydryl groups. In proteins, this bond covalently connects the sulfur atoms of two cysteine residues.

Endoplasmic reticulum A specialized compartment of eukaryotic cells in which extracellular proteins are processed for secretion or inclusion in other cellular compartments.

Glutathione (GSH) A tripeptide, γ -glutamylcysteinylglycine found at high concentrations in cells. It is the major thiol compound in most cells involved in redox reactions and the

protection of cells against reactive oxygen species and toxic compounds.

Oxidation Disulfide bond formation (formally, the loss of electrons) oxidation.

Oxidative folding The coupling of disulfide formation to the folding of a protein into its correct three-dimensional (3-D) structure. Disulfides stabilize protein structure and vice versa.

Protein folding The process by which an unfolded protein gains its 3-D structure.

Reduction Formally, the gain of electrons. Disulfide bonds are reduced to two thiols.

Thiol A sulfhydryl (–SH) group.

Chemistry of Disulfide Formation as a Posttranslational Modification

Disulfide Formation

Extracellular and secreted proteins often contain many disulfides, with pairs of cysteines linked to each other in a specific configuration in the folded protein (Figure 1). Biochemically, disulfide formation is an oxidation (the loss of electrons). Not all of the cysteines in a protein form disulfides. Disulfides form only when the structure of the protein places two cysteines in the proper spatial location and when an oxidizing agent is available. The chemical reaction is reversible, and high concentrations of a reductant can reverse or prevent disulfide formation.

Disulfide Rearrangements

Through a chemical process called thiol–disulfide exchange, one disulfide may serve as an oxidizing agent to form a disulfide between two different cysteines (Figure 2). If this leads to connecting the cysteines in a different configuration, it is termed disulfide isomerization.

Oxidative Protein Folding

Since many disulfides will be buried in the core of the protein and link cysteines that are not adjacent in sequence, disulfide formation and rearrangements often occur as the protein attains a three-dimensional (3-D) structure (protein folding). The coupling of disulfide formation and protein folding is termed oxidative protein folding.

Structure Is Linked to Disulfide Formation

In the 1960s, Anfinsen and his colleagues used the reversible nature of disulfide formation to demonstrate that the primary

sequence of a protein contains sufficient information to define the final, biologically active structure of a protein. Disulfide bonds stabilize protein structure by organizing and destabilizing the denatured protein relative to the native structure. Usually, both the disulfides and noncovalent interactions (hydrophobic interaction, hydrogen bonds, etc.) are needed to specify the structure of ribonuclease A (RNase). Reducing the disulfides or using urea to disrupt the noncovalent structure causes a loss in biological activity. After removing the urea and including an oxidizing agent to reform the disulfides, the protein spontaneously refolds, forming the correct disulfides and a biologically active structure. However, if disulfide formation is permitted without removing the urea, random disulfides form (scrambled RNase) and there is no regain of biological activity. If disulfide formation is inhibited (by including a reducing agent), the native structure does not form when the urea is removed. Disulfide bonds are essential for forming the native structure but when the noncovalent structure is disrupted by denaturants disulfides are usually not sufficient to specify the tertiary structure.

Disulfide Bond Formation during Protein Folding

Even with two disulfides, there are numerous ways to connect the cysteines (Figure 3), and the problem increases greatly as the number of disulfides to be formed increases. Early in protein folding, disulfide formation tends to be error prone. Two types of errors have been found: (1) the disulfides may be formed between the wrong pairs of cysteines or (2) the correct cysteines may be paired but in a temporal order that interferes with the assembly of the rest of the structure. In both cases, the incorrect disulfides are replaced with the correct ones through disulfide isomerization. In the cases examined so far, many incorrect disulfides accumulate early in oxidative folding. These are slowly replaced by correct disulfides through isomerization which requires the breaking and reforming of disulfide bonds.

Figure 1 Disulfide formation and isomerization. An alignment step is needed to bring two sulfhydryl groups from cysteine residues into close proximity. Disulfide formation represents an oxidation where the electrons from disulfide formation must be transferred to an oxidizing agent. Disulfide isomerization does not formally require a change in the oxidation state of the protein; however, a thiol group is needed to initiate and propagate the change in disulfide connectivity.

Figure 2 Structure of disulfide bonds: (a) disulfide bonds cross-link cysteines in various parts of the protein structure, (b) some disulfides (yellow) are exposed to solution in the tertiary structure of the protein but others are buried in the core of the protein and not exposed to solution.

Catalysis of Disulfide Formation

Soon after discovering that native proteins can be regenerated from reduced, denatured ones, Anfinsen realized that *in vitro* oxidative folding was often too slow (hours to days) to be biologically relevant. The resulting search for a biological catalyst for oxidative folding led to the discovery of the first catalyst of protein folding, protein disulfide isomerase (PDI).

Protein Disulfide Isomerase

PDI accelerates the regain of native structure by catalyzing the formation of disulfide bonds and by providing a way to correct mistakes in connecting cysteines. PDI is an enzyme that has both oxidase (disulfide formation) and isomerase (disulfide rearrangement) activities. PDI accelerates thiol/disulfide exchange reactions (Figure 1) with proteins and small-molecule substrates. The final outcome of the reaction will depend on the redox conditions. The catalytic sites are contained

in two thioredoxin homology domains located at each end of the PDI molecule. These active sites, both with the sequence CGHC, have the correct redox potential to effectively catalyze oxidation, reduction, and exchange reactions under the redox conditions of the endoplasmic reticulum. PDI interacts with its protein substrates but in a way that does not direct which cysteines are connected in the substrate. The mechanism involves several rounds of making and breaking disulfide bonds until the final structure becomes resistant to further isomerization of its disulfides.

The Thioredoxin Family

Many of the thiol–disulfide exchange reactions of the cell are mediated by members of the thioredoxin family. This large family of proteins is characterized by an active site sequence of CXXC and an α - β secondary structure. The structure greatly affects the redox potential for reducing the active site disulfide. Thioredoxin, the patriarch of the family, is an excellent reducing agent involved in the biosynthesis of deoxyribonucleotides for DNA synthesis and in helping maintain reduced proteins in the cellular cytoplasm. DsbA, a periplasmic oxidase in bacteria, is an excellent oxidizing agent that inserts disulfides into secreted proteins. The ease of forming the CXXC disulfide varies by a factor of over 10^5 , corresponding to a redox potential difference of more than 0.15 V.

Disulfide Formation in the Cell

Disulfide bond formation state is influenced by the thiol/disulfide redox environment of the cellular compartment where the protein is located. Most disulfides are found in secreted or extracellular proteins where the environment is oxidizing. Generally, the cytoplasm of most cells, bacterial and eukaryotic, is very reducing, due to the high concentration

Figure 3 Generalized mechanism of oxidative protein folding. The initial stages of oxidative folding are error prone and often lead to the connection of cysteines that are not connected in the native structure. Different proteins will generate a different population of misoxidized species which are converted to the native structure (N) by disulfide bond isomerization.

of glutathione (GSH, a tripeptide, γ -glutamylcysteinylglycine) and the low concentration of glutathione disulfide.

Extracellular Proteins

Proteins destined for the extracellular environment acquire disulfides after they are secreted from the cytoplasm during translation. In bacteria, an elaborate system of periplasmic and membrane-bound proteins, comprising the Dsb system, provides the periplasm with oxidizing equivalents to enable disulfide formation and with reducing equivalents and catalytic isomerases to correct errors during protein folding (Figure 4). DsbB couples the bacterial electron transport system to disulfide formation, providing a source of oxidizing agent which are delivered directly to folding proteins by DsbA. Reducing equivalents to enable disulfide isomerization are provided by thioredoxin in the cytosol and transferred across the inner bacterial membrane by DsbD to DsbC, the periplasmic isomerase.

A similar system operates in eukaryotic cells, although all the elements of the system have not been found. Extracellular proteins are synthesized on the rough endoplasmic reticulum and translocated into the lumen (inside) during translation. The lumen of the endoplasmic reticulum is a more oxidizing intracellular compartment than the cytoplasm. Oxidizing equivalents are transferred from Ero1 to PDI and then to the folding proteins. The ultimate source of the oxidizing agent is not yet known. Reducing agents of the endoplasmic reticulum enable PDI and other catalysts to correct any errors in pairing

cysteines by reducing the incorrect disulfide bond. Reducing agents are provided by glutathione, presumably by importing GSH from the cytoplasm. The endoplasmic reticulum has an elaborate quality-control mechanism, which prevents misfolded proteins from exiting the endoplasmic reticulum or directs them to degradation pathways. The error-correction activity of PDI plays a critical role in this system. Depending on the details of the folding mechanism dictated by the primary sequence, different extracellular proteins may use different components of the complex folding and quality-control apparatus of the endoplasmic reticulum to gain their correct 3-D structures, including the disulfide bonds that stabilize the structures.

Disulfide Formation as a Regulatory Mechanism

Because disulfide bond formation is reversible, disulfide bonds can also regulate biological activity through their ability to stabilize specific protein structures. For example, the bacterial transcription factor, OxyR, senses the redox environment of the aerobic bacterial cell through reversible disulfide bond formation linked to the cellular redox state and oxygen metabolism. Reduced OxyR is inactive as a transcription factor and upon oxidation and disulfide formation, the transcription factor can regulate the transcription of genes involved in the protection of the cell against oxidative stress and reactive oxygen species. Similar mechanisms operate in eukaryotic cells.

Figure 4 Disulfide bond formation in bacterial and eukaryotic cells. In both cells, the major pathways for disulfide formation are located in specialized cellular compartments where the redox state of the environment is maintained in a more oxidized state than the cytosol.

Glossary

Deamination The hydrolytic elimination of an amino group from a base or other compound.

Free radical A molecule, ion, or an atom having an unpaired valence electron that is typically highly reactive and short lived.

Hydrolysis Chemical decomposition in which a compound is split into other compounds by reaction with water.

Schiff base The metastable product of the chemical association of an aldehyde with a primary amine.

Introduction and Overview

Base excision DNA repair (BER) is one of the four major DNA repair pathways of mammalian cells, and in biology generally. BER systems process a majority of smaller lesions that do not greatly distort the helical structure of DNA. By contrast, nucleotide excision repair seems to be directed at lesions that cause significant helix distortion (e.g., pyrimidine photodimers), while mismatch repair detects primarily replication errors and provides ancillary functions in some other pathways, and recombinational repair and end-joining pathways handle DNA double-strand breaks. Additional repair pathways correct very specific types of DNA damage, such as the demethylation proteins that directly reverse mutagenic products such as O6-methylguanine or 1-methylthymine.

The DNA lesions targeted by BER include most of those due to oxidative damage, a major threat in aerobic organisms; N-alkylated bases that result from reactions with metabolites and environmental agents; and the DNA lesions that result from hydrolytic reactions that occur relentlessly in all organisms (e.g., depurination resulting in base loss or deaminations that alter the composition of heterocyclic bases). Specific examples of DNA damage efficiently processed by BER include the deamination product uracil in DNA, derived from cytosine; the oxidative lesions 8-oxo-guanine (8-oxoG; structure 5 in Figure 1), thymine glycol (structure 1 in Figure 1), and the ring-fragmentation product *N*-(2,4-diamino-6-oxo-5H-pyrimidin-5-yl)formamide or formamidopyrimidine (structure 2 in Figure 1); and the alkylation product N3-methyladenine (structure 7 in Figure 1). See Figure 1 for the structures of selected base alterations and abasic sites.

The steps of the simplest BER pathway were worked out for the repair of uracil residues in DNA, and they apply to many other lesions. Uracil in DNA is recognized by uracil–DNA glycosylase, the first such enzyme discovered, which hydrolyzes the base–sugar glycosylic bond. Several forms of uracil–DNA *N*-glycosylase are now known and, in total, 10 DNA glycosylases act on a range of oxidized, alkylated, or hydrolytic base derivatives. In addition, the MUTHY glycosylase (homologous to *Escherichia coli* MutY) specifically excises undamaged adenine opposite 8-oxoguanine residues, which offsets possible mutation when an oxidized DNA template is copied by DNA polymerase.

Removal of damaged or inappropriate bases by DNA glycosylases yields abasic sites (structure 3 in Figure 1) (specifically, apurinic or apyrimidinic sites, which we will term collectively AP sites). These are recognized by AP endonuclease enzymes, the most common forms of which cleave the 5′ phosphodiester of the abasic site to generate a single-strand break bracketed by a nucleotide-3′-hydroxyl and 5′-deoxyribose-5-phosphate ester (the AP site). Other enzymes may also incise abasic sites, which might lead to alternative processing (see section [The Core Enzymes of BER](#)).

The 3′-terminus at the AP endonuclease-generated strand break is then extended by DNA polymerase to replace the missing nucleotide; in mammalian cells, this reaction is carried out primarily by DNA polymerase β (Polβ) during BER in the nucleus. Before DNA ligation can complete the repair, the 5′-abasic residue or a displaced single strand containing it must be removed, and there are alternative subpathways that achieve this removal. Finally, DNA ligase joins the ends to restore the original DNA structure.

Sources and Occurrence of Lesions Handled by BER

As noted in the preceding section, there are important endogenous sources of DNA lesions that are processed in BER pathways. Some sources can be modulated if not completely eliminated (e.g., oxygen radicals in aerobic organisms), but at least one is simply unavoidable: the water that drives hydrolytic depurination and base deamination reactions. Beyond this endogenous burden of lesions, DNA is subject to damage by many environmental agents, including ultraviolet and ionizing radiation (e.g., X-rays) and environmental compounds such as methyl chloride. Still other environmental agents exacerbate cellular processes to inflict DNA damage. Important examples are the redox-cycling quinones and the herbicide paraquat, which set up a ‘redox cycle’ dependent on cellular reductases to generate superoxide radicals, thus exerting powerful oxidative stress in the cell.

Many of the same lesions result from both endogenous and environmental sources. For oxidative DNA damage, dozens of different base lesions have been identified, largely through the work of radiation chemists. Most well known among these are the highly mutagenic 8-oxoG, thymine glycols,

Figure 1 Structures of some selected DNA lesions processed by BER. Note that many more have been described: the examples shown here were chosen because their repair has been extensively characterized, or they have notable biological importance. 1, thymine glycol (representing multiple stereoisomers); 2, the formamidopyrimidine *N*-(2,4-diamino-6-oxo-5H-pyrimidin-5-yl)formamide; 3, an AP site (actually a mixture of the *a* and *b* anomers, which are in equilibrium); 4, 2-deoxyribonolactone (dL); 5, 8-oxoguanine (8-oxoG); 6, 5-hydroxymethyluracil; 7, 3-methyladenine; 8, a 3'-phosphoglycolate ester.

formamidopyrimidine derivatives of both guanine and adenine, and 5-hydroxymethylcytosine (structure 6 in [Figure 1](#)), but none constitutes more than a few percent of the total oxidative damage. Chemical oxidants such as H_2O_2 produce most of the same base lesions as ionizing radiation. Similarly, DNA alkylation produces an array of lesions, with 3-methyladenine having a substantial cytotoxic effect, while the more abundant 7-methylguanine accounts for a much greater proportion. It should be noted, though, that 7-methylguanine can undergo alkali-catalyzed opening of the imidazole ring to generate a methylated formamidopyrimidine, analogous to the fragmented purines formed by oxygen radicals.

Abasic sites are generated not only by DNA glycosylases, but also by acid-catalyzed hydrolysis liberating undamaged purines from DNA and, to a much lesser extent, pyrimidines. Modified bases such as 3-methyladenine have destabilized glycosylic bonds that promote their release. *In vitro* DNA depurination measurements gave an estimated rate of about 10 000 hydrolytic depurination events per day in a mammalian genome. Other endogenous and environmental sources of DNA damage would add to this burden. Free radicals also directly generate oxidized forms of abasic sites, including fragmentary products. BER enzymes deal with these lesions, with some oxidized abasic residues requiring processing by a special subpathway of BER.

Some radiomimetic drugs used in chemotherapy, such as bleomycin and calicheamicin, operate by oxidizing the deoxyribose sugar in DNA, leading to loss of the base. The cytotoxic

effectiveness of these agents depends on their ability to generate such lesions in clusters, which is also true of X-rays, with the hallmark production of double-strand breaks. Double-strand breaks and probably other types of lesion clusters need the intervention of recombinational repair pathways for their correction.

Finally, there are biological processes in the cell that actively generate BER lesions. Although the enzyme dUTPase (dUTP pyrophosphatase, the human *DUT* gene product) efficiently excludes dUTP from the pool of DNA synthesis precursors, small amounts of this nucleotide are inserted by DNA polymerases, which use them relatively efficiently. The nuclear form of mammalian uracil-DNA *N*-glycosylase is associated with replication centers, where it is poised to remove the occasional uracil residue incorporated during DNA synthesis. It is worth noting that uracil incorporated in this way, opposite template A residues, is not *per se* mutagenic. This situation contrasts with uracil formation by the deamination of cytosine in duplex DNA to generate a G:U base pair which, if processed by replication, would produce an A:U base pair in one product, and eventually an A:T transition mutation. Active mutagenic deamination occurs in the vertebrate immune system during antibody diversification in germinal centers (somatic hypermutation) and immunoglobulin class switching, where the mutagenic effect is desirable. It remains uncertain why BER does not counteract this process effectively.

The nucleotide pool can also react with the same agents that damage DNA itself. In this way, some 8-oxo-dGTP is generated,

which can be incorporated by DNA polymerases, occasionally opposite A in the template in a mutagenic reaction. This threat is largely offset by MutT-type (mammalian MTH1) enzymes that hydrolyze 8-oxo-dGTP to 8-oxo-dGMP, which is, thus, analogous to the cleansing of the nucleotide pool carried out by dUTPase. Localization of mammalian MUTYH to replication forks provides a second level of defense against this type of mutagenesis.

The-Core Enzymes of BER

DNA Glycosylases

To date, 11 distinct DNA glycosylase enzymes have been identified, which can be put into two broad functional categories (Table 1). All of the enzymes excise the target base by cleaving the N-glycosylic bond that connects the base to C1' of the deoxyribose sugar, resulting in an AP site in DNA. Most of the 'pure' glycosylases activate water for the hydrolysis reaction. However, five enzymes have both DNA glycosylase activity and AP lyase activity, enabling them to cleave the AP sites they produce, as well as AP sites generated by other routes. These enzymes act through a covalent Schiff base intermediate, linked to an amine (usually lysine) in the enzyme. The Schiff base intermediate is resolved by hydrolysis, which leaves a 2–3 unsaturated abasic residue attached to a 3' end at the nicked site.

This glycosylase/lyase group corresponds to the enzymes that act on oxidative lesions, oxidized or fragmented forms of purines and pyrimidines, including 8-oxoG, thymine glycols, and formamidopyrimidines. The prompt introduction of a strand break by these enzymes might provide a generalized mark of the damage, although that idea does not address why the glycosylases for uracil and methylated purines do not share

such an activity. Moreover, although the AP lyase activities can be detected *in vitro*, their contribution to AP site cleavage *in vivo* is unclear.

The MUTYH glycosylases are unique, in that they share structural features with the glycosylase/lyase enzymes, but act only as glycosylases. It seems likely that the lyase activity was lost as this enzyme evolved, which again puts the question of the role of the lyase functions in general.

Collectively, the DNA glycosylases remove a wide array of lesions, and some are present both in the nucleus and in mitochondria (see section BER in Mitochondria). The degree of specificity varies among the enzymes. Uracil–DNA glycosylase acts on a fairly narrow range of structurally related substrates, and maximally on uracil itself. By contrast, Nth-type enzymes remove a broad spectrum of lesions derived from pyrimidines, from thymine glycol and pyrimidine hydrates, to the fragmentation/contraction product 5-hydroxy-5-methyl hydantoin, and even urea, a minimal oxidation fragment. Evolution has further refined specificity in some cases. Methylpurine glycosylases are most active on 3-methyladenine, but they can also excise hypoxanthine (deaminated adenine). However, the mammalian MPG enzymes (Table 1) also have significant activity against longer alkyl chains (ethyl, propyl) and some exocyclic adducts (1, N6-etheno-adenine), and remove these more effectively than the *E. coli* enzyme. The bacteria instead contain a second protein AlkA that expands the repertoire of alkylated substrates.

AP Endonucleases

We distinguish AP endonucleases as enzymes that activate water to mediate cleavage of the phosphodiester bonds, and produce a nick with 5'-deoxyribose-5-phosphate. This contrasts with the glycosylase/lyases that produce nicks with the unsaturated abasic derivative attached to a 3' end (Figure 2). Cleavage of the latter type can even occur nonenzymatically in reactions catalyzed by small primary amine compounds.

Enzymatic and molecular genetic studies have revealed that AP endonucleases comprise two phylogenetic groups, each including both prokaryotic and eukaryotic members (Table 2). The prototypic proteins of the two groups are the two main AP endonucleases of *E. coli*: exonuclease III, encoded by the *xth* gene, and endonuclease IV, encoded by the *nfo* gene. The former enzyme was first discovered as an exonuclease and 3'-phosphatase; hence, the name exonuclease III. Later, the enzyme was shown to have an AP endonuclease activity about equal to its exonuclease activity. Endonuclease IV represents about 5% of the total AP endonuclease activity in *E. coli* under normal growth conditions, but the enzyme is strongly inducible in response to oxidative stress. Exonuclease III and endonuclease IV are structurally unrelated and engage the AP site in DNA differently, but they yield the same cleavage product.

The major AP endonuclease of the budding yeast *Saccharomyces cerevisiae* is termed Apn1 and is a relatively close homolog of endonuclease IV, but with a C-terminal extension that contains the nuclear localization sequence. Apn1 functions in yeast BER, and enzyme-deficient mutants are hypersensitive to agents that generate AP sites and base damage processed by BER, such as H₂O₂ and methylating chemicals. A second AP endonuclease is present in *S. cerevisiae* at low levels: the

Table 1 Human DNA glycosylases^a

Enzyme name	Associated AP lyase	Subcellular location ^b	Major substrates ^c
UNG	No	N/M	Uracil (U)
SMUG1	No	N	U
MBD4	No	N	U or thymine (T) opposite the guanine (G) at CpG sequences
TDG	No	N	U, T, etheno-C opposite G
OGG1	Yes	N/M	8-oxoG opposite cytosine (C)
MYH	No	N/M	Adenine (A) opposite 8-oxoG
NTH1	Yes	N/M	Ring-saturated or fragmented pyrimidines
MPG	No	N	3-methyl-A, etheno-A, hypoxanthine
NEIL1	Yes	N	Thymine glycols
NEIL2	Yes	N	Oxidative products of pyrimidines
NEIL3	Yes	N	Oxidative products of pyrimidines

Figure 2 Branching pathways of BER. The topmost branch depends on the type of AP site incision: AP endonuclease (left) vs. AP lyase (right; the lyase Schiff base intermediate is shown). LP-BER flows down the left, and single-nucleotide BER on the right. See text for details. RFC, the loading activity for PCNA protein. Reproduced from Schärer OD (2003) Chemistry and biology of DNA repair. *Angewandte Chemie International Edition in English* 42: 2946–2974.

Apn2/Eth1 protein. This enzyme is much less active than Apn1 and may function as a backup activity, or perhaps it acts in an as-yet-unknown pathway. An Apn1-type AP endonuclease also seems to be the main such enzyme in the nematode *Caenorhabditis elegans*, where it is encoded by the *apn-1* gene. Suppression of this enzyme by RNA interference (RNAi) reproduces in *C. elegans* similar phenotypes of BER deficiency as those observed in yeast.

AP endonucleases of the exonuclease III family seem to be more common in metazoan organisms than endonuclease IV homologs appear to be. The predominant enzyme in mammalian cells belongs to this family, and is usually termed APEX or Ape1 protein. Ape1 proteins contain a ~280-residue segment homologous to exonuclease III, with a ~60-residue extension at the N-terminus that contains the nuclear localization signal. Ape1 is a robust AP endonuclease, even more active than its bacterial counterpart, and it acts on a variety of AP site

derivatives including oxidized products such as 2-deoxyribonolactone (dL; structure 4, Figure 1). The human protein was able to supply the AP endonuclease function in enzyme-deficient *E. coli* or *S. cerevisiae*, but establishing its role in mammalian cells was initially hampered by an inability to obtain stable *APE1*-null cell lines. *APE1*-knockout mutations cause embryonic lethality in mice, underscoring the important role played by this protein. Eventually, RNAi and conditional knockout techniques were used to show that the DNA repair activity of Ape1 is essential in mammalian cells. This contrasts with microbes, where AP endonuclease-deficient mutants show full viability; this difference may relate to the much greater amount of cellular DNA that has to be maintained in mammalian cells. Evidently, enough DNA damage accumulates under normal conditions in mammalian cells to cause proliferation arrest and apoptosis when Ape1-dependent BER is severely limited.

Table 2 Core BER enzymes in DNA base excision repair^a

Organism	Protein			
	ExoIII-like	EndoIV-like	DNA polymerase	DNA ligase
<i>Escherichia coli</i>	Xth	Nfo	Pol I	Lig
<i>Caenorhabditis elegans</i>		apn-1		
<i>Drosophila melanogaster</i>	Rrp1			
<i>Arabidopsis thaliana</i>	ARP			
<i>Danio rerio</i>	Apex1			
<i>Xenopus tropicalis</i>	APEX1			
<i>Mycobacterium genitalium</i>		nfo		
<i>Saccharomyces cerevisiae</i>	Apn2/Eth1	Apn1	Pol2 or Pol3	Cdc9
<i>Schizosaccharomyces pombe</i>	apn2/eth1	apn1	cdc6 or cdc20	cdc17
<i>Mus musculus</i>	Apex1			
<i>Rattus rattus</i>	Apex1			
<i>Cricetus griseus</i>	Apex1			
<i>Bos taurus</i>	APEX1			
<i>Homo sapiens</i>	APEX1 or Ape1		DNA polymerase β or δ/ϵ	Ligase I or III

^aWe have included only enzymes with demonstrated biochemical activity.

End-Processing Enzymes

Oxidative agents including ionizing radiation produce strand breaks with 3' termini that are unusable by DNA polymerases. A notable example is 3'-phosphoglycolate esters, which contain only the former 4' and 5' carbons of deoxyribose (structure 8 in Figure 1). The strand breaks produced by the antitumor drug bleomycin produce the same lesion. In both prokaryotic and eukaryotic cells, these esters are excised by AP endonucleases to provide active 3'-OH primers for DNA repair synthesis. Bacteria deficient in exonuclease III accumulate unrepaired 3'-phosphoglycolate esters when oxidative DNA damage is inflicted by H₂O₂. Although Ape1 is the predominant 3'-phosphoglycolate diesterase activity in mammalian cell extracts, other enzymes have recently been implicated in repair of this lesion, including Aprataxin, Artemis, and the tyrosyl-phosphodiesterase TDP1 that also corrects some abortive topoisomerase intermediates.

Oxidative agents also generate strand breaks with 3'-phosphate and 5'-hydroxyl residues. Such termini block DNA polymerases and can even bind them unproductively. The AP endonucleases of *E. coli* and *S. cerevisiae* readily remove these blocking phosphates, but the mammalian enzymes have far less activity. Instead, the major 3'-phosphatase in mammalian cells is the polynucleotide kinase-phosphatase PNKP, which also phosphorylates the 5' hydroxyls via a separate kinase domain. Note that this process at an oxidative strand break still leaves a one-nucleotide gap requiring DNA repair synthesis.

The glycosylase/lyase enzymes generate products that require 3' processing before DNA repair synthesis can commence. Many of these enzymes leave unsaturated deoxyribose (2,3-didehydro-2,3-dideoxyribose) at the 3' terminus of the nick, which is also the product of nonenzymatic β -elimination at AP sites. Their removal is accomplished by Ape1. Some glycosylase/lyase enzymes (*E. coli* Fpg, and the mammalian NEIL proteins) can also follow β -elimination with a second reaction, δ -elimination, that leaves only a 3'-phosphate that must be excised by PNKP.

DNA Polymerases

Multiple DNA polymerases participate in single-nucleotide and long-patch (LP)-BER (Figure 2). In the mammalian nucleus, the former pathway depends largely on DNA polymerase β , but DNA polymerase λ acts as a backup activity. The insertion of a single nucleotide displaces only the 5' abasic residue at the break. For the LP-BER pathway, DNA polymerase β may also participate, particularly in the early stage, but DNA polymerases δ and ϵ mediate the repair in concert with proliferating cell nuclear antigen (PCNA). LP-BER synthesis results in displacement of the downstream 5' end to form a flap structure (Figure 2).

5'-Deoxyribose-5-Phosphate Lyase

The abasic residue displaced by DNA repair synthesis must be removed before ligation can complete the BER reaction. For the single-nucleotide pathway, this is accomplished in bacteria by Fpg protein, in a reaction analogous to its incision of an intact AP site. In mammalian cells, the excision is mostly dependent on DNA polymerase β , which uses a lysine in its N-terminal domain to carry out the lyase reaction (5'-dRp lyase; Figure 3). This seems to be the more important function of polymerase β in single-nucleotide BER, in that resistance to monofunctional alkylating agents in *POLB*-knockout cells is provided by expression of the separated N-terminal lyase domain, but not when only the polymerase domain is expressed. Polymerases ι and λ also have 5'-dRp lyase activity. It should be noted that this activity is problematic for processing certain oxidized abasic sites (see section Special Problems in BER).

Flap Endonuclease

The flap structure generated by DNA synthesis in LP-BER renders the 5'-dRp residue unavailable for removal by the 5'-dRp lyase of polymerase β . Instead, this structure must be removed by Flap endonuclease (FEN1 protein), which incises the displaced single strand at its junction with double-stranded DNA (Figure 2).

Figure 3 The 5'-dRp lyase activity of DNA polymerase β and cross-link formation with dL. Lysine-72 in the N-terminal domain of the enzyme attacks C1 of an AP site to produce a Schiff base intermediate, which is then hydrolyzed to release the enzyme, the abasic residue and the DNA in overall β-elimination reaction (upper pathway). Attack of the C1 of dL leads to an amide bond, which traps the protein on the DNA (lower pathway). Reproduced from Demple B and DeMott MS (2002) Dynamics and diversions in base excision DNA repair of oxidized abasic lesions. *Oncogene Reviews* 21: 8926–8934.

Like polymerases δ and ε, this enzyme is also a main player in DNA replication, where it participates in the removal of Okazaki fragments formed during lagging-strand synthesis.

DNA Ligases

Two vertebrate DNA ligases are involved in BER, ligase I and ligase III. Each interacts with a partner protein during its reaction in BER. DNA ligase I interacts with PCNA and DNA ligase IIIα forms a stable complex with XRCC1 protein. Although XRCC1 does not itself have enzymatic activity, without this protein ligase III is destabilized; XRCC1 also mediates the interaction of the ligase with DNA polymerase β during single-nucleotide BER. Ligase I participates in LP-BER; it is still another protein (such as FEN1 and PCNA) recruited from replication.

Coordination among BER Proteins

Numerous pairwise protein interactions can coordinate the reactions of BER. Many of the proteins in this pathway exhibit relatively strong product binding, such that they need to be displaced in order for the process to proceed. Several mammalian DNA glycosylases have been reported to interact with Ape1 protein, which accelerates the glycosylase reactions. In many cases, this effect may occur by the Ape1-mediated incision of their product AP sites. Similarly, Ape1 binds its 5'-incised abasic product more tightly than it does an intact AP site. This bound Ape1 recruits DNA polymerase β, and in the process

strongly activates the 5'-dRp lyase activity. DNA synthesis and dRp excision facilitate the departure of Ape1, and bound DNA polymerase β recruits the XRCC1-ligase IIIα complex to promote ligation. In LP-BER, PCNA interacts with both the DNA polymerases and with FEN1 protein to coordinate the overall repair reaction. Collectively, these interactions may prevent the accidental release of repair intermediates that could undergo aberrant reactions or trigger checkpoint pathways.

Special Problems in BER: A Rationale for the LP Pathway

When LP-BER was first discovered, the utility of this pathway was not obvious. When examined in cell-free extracts, lesions such as uracil, which in principle should be well handled by single-nucleotide BER, nevertheless undergo significant amounts of LP-BER (although the single-nucleotide pathway predominates). Some evidence suggested that modified forms of deoxyribose, perhaps oxidized derivatives, might require LP-BER. One such form was identified as dL (Figure 1), a major abasic lesion formed by radiation or chemical oxidation. Synthetic DNA substrates containing a single dL residue were readily cleaved by Ape1 protein, about as efficiently as an ordinary AP site. However, subsequent reaction with DNA polymerase β revealed that the enzyme forms a stable DNA-protein cross-link during attempted excision of the abasic residue. Instead of the hydrolysis-sensitive Schiff base formed during the normal 5'-dRp lyase reaction, the polymerase forms

a stable amide bond with its catalytic lysine-72 (Figure 3). This DNA–protein cross-link is resistant to removal by various enzymes, including FEN1 protein. However, substrates with a dL residue trigger the activation of LP-BER, such that this lesion is processed virtually completely by this pathway. As dL is produced in amounts similar to the other major oxidative lesions, LP-BER would be biologically essential for correction of this lesion. Other naturally occurring lesions that require LP-BER remain to be identified.

Other polymerases with 5'-dRp lyase activity also form cross-links with the incised dL lesion (see section [BER Pathways in Mitochondria](#)). In addition, attack on an unincised dL residue by some AP lyase enzymes might also produce stable DNA–protein cross-links. The mammalian enzymes do not seem to be prone to this reaction, however, and only endonuclease III of *E. coli* (the NTH1 counterpart) was reported to form stable cross-links with dL. None of the mammalian AP lyases was able to incise a dL residue.

BER Pathways in Mitochondria

Mitochondrial DNA (mtDNA) is as essential for eukaryotic function as is the nuclear genome, so it might seem obvious that systems to maintain mtDNA would be present. Moreover, mtDNA replication proceeds even in nonproliferating cells, which implies that maintenance of the mtDNA template is required in all tissues at all times. A particular threat to mtDNA may be oxidative damage, as the organelle is the site of oxidative phosphorylation. Although mitochondria seem to lack pathways available in the nucleus, notably nucleotide excision repair activity or proteins, several DNA glycosylases (Table 1) and Ape1 protein are present. In addition, the mtDNA polymerase γ has its own 5'-dRp lyase activity, and a form of DNA ligase III is present in the mammalian mitochondria. Thus, the basic single-nucleotide BER machinery is present to handle some deamination and oxidative lesions.

However, oxidation produces dL residues in amounts similar to 8-oxoG, such that LP-BER may also be needed. Indeed, DNA polymerase γ also forms stable cross-links with Ape1-incised dL in a manner analogous to polymerase β (Figure 3). As in the nucleus, this problem is averted by the presence of LP-BER activities, which led to the discovery that FEN1 protein is present in mitochondria. Mammalian mitochondria also contain a second activity that can process flap-containing intermediates formed during LP-BER, an isoform of the DNA2 protein. This distribution contrasts with *S. cerevisiae*, in which DNA2 seems to be exclusively nuclear.

The localization of the various BER proteins to mitochondria occurs by both classical and nonclassical pathways. In the case of uracil glycosylase, a specific isoform of the protein generated via alternative messenger RNA splicing is transported in the signal-peptide pathway. In the case of Ape1 protein, removal of its N-terminal nuclear-targeting sequence may allow the C-terminal mitochondrial transport sequence to function. The mitochondrial targeting sequence of FEN1 has not been identified, but a potential mitochondrial import determinant was identified in mammalian DNA2. It is unknown whether the distribution of these enzymes is altered under different conditions.

Other Functions of BER Proteins

The Ape1 AP endonuclease was independently identified as a factor termed Ref-1, which activates *in vitro* DNA binding by various transcription factors. The detailed mechanism of this reaction has not been determined, but it seems dependent on one or more cysteines in the N-terminal ~100 residues of the protein. As most of these residues are folded inside the native Ape1 structure, some partial unfolding may be required for Ref-1 activity. Some *in vivo* experiments in cell culture suggest that Ref-1 depends on reducing power from thioredoxin.

Ape1 may also directly regulate several promoters including that of the parathyroid hormone gene by binding upstream control elements. This binding appears to depend on two N-terminal lysine residues, which are partially acetylated in cells. Additional function of these acetylation sites has been proposed for an Ape1-specific function in the nucleolus, the site of ribosomal RNA synthesis.

BER Genes and Disease Risk

In view of the apparently fundamental role of BER pathways, it is surprising that deletion of individual DNA glycosylase genes in mice does not produce dramatic increases in rates of spontaneous cancer. For the uracil glycosylase gene, a modest elevation in certain cancers is observed in older animals, and for other glycosylase genes, their ablation increases the rate of tumor formation in response to carcinogens. One possibility is that there is redundancy for the most important lesions among the glycosylase enzymes. However, for OGG1 and MUTYH, human polymorphisms have been linked to increased rates of some human cancers. Additional studies point to possible contributions to cancer by polymorphisms affecting other BER proteins, such as XRCC1. It is unclear to what extent these effects may be due to alterations of nuclear as opposed to mitochondrial function.

In contrast to the glycosylases, all the genes of the central BER pathway are essential, complicating efforts to develop mouse models of defects in their activity. It may also be that carcinogenesis would not be the most prominent effect of such defects; for example, the demonstrable roles of some BER proteins in mtDNA maintenance may give effects in longevity and the aging process.

Some of the DNA end-processing enzymes have connections to human disease. Thus, PNKP mutations cause various neurological defects, which underscores the general importance of pathways to correct single-strand breaks in DNA. Repair of mtDNA would also be especially important in this context.

Conclusion

The incessant production of DNA lesions by spontaneous and endogenous reactions can be lethal in the absence of active BER functions. In addition, unrepaired lesions trigger mutations due to misreading during replication or the activity of translesion polymerases. BER pathways handle a broad variety of hydrolytic, oxidative, and methylation lesions through branch-point pathways that either replace just one nucleotide or generate

a multinucleotide repair patch (LP-BER). Many lesions can be handled by the single-nucleotide branch, but the LP-BER branch is necessary to process at least one type of oxidized abasic site. DNA glycosylases remove damaged bases or, in some specific cases, conventional DNA bases that are inappropriately positioned. Glycosylases produce AP sites, thus funneling a multitude of different lesions into a central pathway. The central pathway BER enzymes occur universally in nature, and in mammalian cells, they are essential even at the cellular level.

Glossary

Adduct Chemical group covalently attached to a DNA nucleotide; same as a lesion.

Alkylating agent Chemical compound that transfers an alkyl group to another compound or molecule.

DNA base The purine or pyrimidine group in a nucleotide.

DNA base-flipping A common strategy used by enzymes to gain access to nucleotide substrates in double-stranded DNA, whereby a base is rotated out of the DNA helix and into the enzyme active site pocket.

Lesion Chemical group covalently attached to a DNA nucleotide; same as an adduct.

Nucleotide Compound that consists of a nitrogenous base, a sugar, and one or more phosphate groups to form the basic DNA building blocks of guanine, adenine, thymine, or cytosine.

Purine A heteroaromatic compound, present in adenine and guanine, composed of carbon, hydrogen, nitrogen, and oxygen atoms to form fused five- and six-membered rings.

Pyrimidine A heteroaromatic compound, present in thymine and cytosine, composed of carbon, hydrogen, nitrogen, and oxygen atoms to form six-membered rings.

Introduction

DNA-alkylation lesions are among the most common types of DNA damage within cells. If unrepaired, some have serious mutagenic, and even cytotoxic, consequences. Fortunately, cells are protected by several DNA repair mechanisms. However, this repair can be adverse to certain cancer-alkylating therapies, underscoring the importance of understanding DNA alkylation damage and its repair. Here we discuss common types, causes, biological effects, and repair mechanisms for cellular DNA alkylation damage.

Types, Causes, and Deleterious Effects of DNA-Alkylation Damage

DNA base exocyclic oxygens and most of the ring nitrogens are susceptible to alkylation to varying degrees. DNA phosphate backbone oxygens are also susceptible to methylation, leading to methylphosphotriesters. In cells, methylation is most common, but larger adducts can also form, depending on the alkylating agent. Alkylating agents work by either unimolecular nucleophilic substitution (S_N1) or bimolecular nucleophilic substitution (S_N2), with the reaction mode determining the alkylation proportion at different sites. The predominant lesions formed by most alkylating agents are the innocuous 7-methylguanine (7mG) and the highly cytotoxic 3-methyladenine (3mA) lesions. In addition, S_N2 agents, such as methyl methanesulfonate (MMS) (Figure 1) and methyl halides, produce 1-methyladenine (1mA) and 3-methylcytosine (3mC), largely in single-stranded (ss) DNA and RNA. S_N1 agents, such as *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) and *N*-methyl-*N*-nitrosourea (MNU) (Figure 1), react more readily

with DNA oxygens to produce larger quantities of the highly mutagenic and cytotoxic O^6 -methylguanine (O^6 -mG) and the less prevalent but more mutagenic O^4 -methylthymine (O^4 -mT) lesions. The biological effects resulting from DNA alkylation include the alteration of DNA structure and function, DNA strand breaks, and apoptosis. The most common types of DNA-alkylation damage, along with their biological effects and known repair mechanisms, are listed in Table 1.

DNA-alkylation damage arises from several sources. One source is the endogenous methyl donor *S*-adenosylmethionine (SAM), an S_N2 agent that generates the same DNA-alkylation products as MMS, but with a 2000-fold weaker reactivity. SAM is the methyl donor for the majority of *in vivo* enzymatic methylation reactions, and it also spontaneously methylates cellular nucleic acids and proteins at a low but significant rate due to its high transfer potential. Another source is environmental toxins. The most abundant are S_N2 methyl halides from decaying vegetation and biomass burning. Other toxins are potentially carcinogenic S_N1 nitrosamines generated by reacting nitrite with amines and amides in food or decaying matter and found in drinking water, diet, nicotine metabolites, or occupational hazards from industrial processes. A third source is chemotherapeutic alkylating drugs that cause cancer cell apoptosis. The first class of these drugs are methylating agents that produce various DNA monoadducts, including lethal O^6 -mG, which causes apoptosis via the DNA mismatch repair (MMR) pathway (discussed later). The second class are chloroethylating agents that form several DNA and protein adducts. The most toxic one results from guanine O^6 chloroethylation, followed by spontaneous cyclization to yield an unstable N^1, O^6 -ethylguanine intermediate, which readily reacts with the opposing cytosine N3 to form a DNA G–C crosslink that inhibits DNA replication and transcription and causes DNA double-strand breaks and apoptosis.

Repair of DNA-Alkylation Damage by Base Excision Repair

The DNA base excision repair (BER) pathway is the major repair mechanism for most alkylation damage. It repairs alkylated bases with destabilized N-glycosylic bonds, such as N³- and N⁷-substituted alkylpurines and O²-substituted alkylpyrimidines. BER is initiated through the recognition and excision of modified bases by hydrolysis of the N-glycosylic bond by lesion-specific DNA glycosylases to create DNA abasic (AP) sites. Next, the AP site is incised at the 5'-side by AP endonuclease or 3'-side by AP lyase, followed by 5'- or 3'-phosphodiesterases to remove the remaining sugar phosphate at the DNA termini. Finally, DNA polymerase fills the gap of one to several nucleotides and DNA ligase seals the nick.

DNA glycosylases that recognize alkylated bases are found in eukaryotic and prokaryotic organisms. The five known classes of these glycosylases are represented by: (1) 3mA DNA glycosylase I (*Escherichia coli* and *Salmonella*

typhi TAG), (2) 3mA DNA glycosylase II (*E. coli* AlkA), and (3) *Helicobacter pylori* 3mA DNA glycosylase III (MagIII), all belonging to the helix-hairpin-helix (HhH) superfamily of DNA glycosylases, (4) human AAG, and (5) prokaryotic HLR 3mA DNA glycosylases (*Bacillus cereus* AlkC and AlkD) (Figure 2). Also, methylated purines are excised by *Thermotoga maritima* methylpurine DNA glycosylase II (MpgII) and some enzymes of the endonuclease III (Nth) DNA glycosylase family. All known alkylbase glycosylases remove 3mA, but with varying efficiency depending on the surrounding DNA sequence. TAG, AlkA, MagIII, and AAG use similar substrate recognition mechanisms of DNA distortion, nucleotide flipping (usually ~180°), and DNA intercalation by amino acid side chains for stabilization, whereas a different mechanism is likely employed by AlkC and AlkD.

3mA DNA Glycosylase I (*E. coli* and *S. typhi* TAG)

The constitutively expressed TAG protein of the HhH family of DNA glycosylases removes 3mA, and also 3mG with lower affinity, but not 7mG. TAG is important for initial cellular protection against sudden alkylation challenge. TAG is a globular protein, with an α -helical domain containing the HhH motif, and a Zn²⁺-binding domain that connects the protein N- and C-termini (Figure 2(a)). The lesion-binding pocket is at the domain interface and contains specific substrate interactions. Despite structural similarity to other HhH-family glycosylases, TAG has notable features that distinguish it as an

outlier, including a different strategy to access the damage site: intercalation of both DNA strands by a single hairpin loop and impartial rotation of the target nucleotide into its active site, and catalysis by a glutamic acid rather than the conserved aspartate of other known HhH glycosylases. TAG likely detects 3mA lesions through its extensive interactions with both DNA strands and uses a ground-state destabilization mechanism for the catalysis of base excision.

3mA DNA Glycosylase II (*E. coli* AlkA)

AlkA is an inducible HhH-family protein that recognizes N^3 - and N^7 -alkyl purines, O^2 -alkyl pyrimidines, deaminated adenine (inosine), and the cyclic ethenoadducts 1, N^6 -ethenoadenine (ϵ A) and 3, N^4 -ethenocytosine (ϵ C). AlkA family members include *E. coli* AlkA, *Saccharomyces cerevisiae* Mag, *Schizosaccharomyces pombe* Mag1 and Mag2, and *B. cereus* AlkE. *E. coli* AlkA is a globular three-domain protein (Figure 2(b)). The active site with conserved catalytic Asp238 is inside a large hydrophobic cleft between two domains. This active site cleft is unusually rich in aromatic residues and AlkA likely uses this abundance of electrons, in combination with shape and H-bonding, to recognize electron-deficient substrates. Leu125 wedges out alkylated nucleotides from DNA, accompanied by an induced 66° DNA bend and minor groove widening. AlkA primarily contacts the DNA damaged strand, anchoring it through a sodium ion bridge with the HhH motif. The extrahelical alkyl base is stabilized by a cation- π interaction with Trp272. Asp238 likely stabilizes a carbocation intermediate for catalysis to proceed through an S_N1 -type mechanism. Excision selectivity may result from the weakened glycosylic bond of the positively charged base.

H. pylori 3mA DNA Glycosylase III (MagIII)

H. pylori MagIII is highly specific for 3mA removal and shares 32% sequence identity with *T. maritima* MpgII, but its inability

to remove 7mG or hypoxanthine from DNA makes it more functionally similar to TAG. MagIII is similar in structure to HhH-family glycosylases (Figure 2(c)), with the notable differences that it lacks an iron sulfur cluster or other additional domains, and its C-terminal domain contains a longer helix that is part of the substrate-binding site and a lysine carbamylation site. The lesion-binding pocket is lined by hydrophobic residues and is specific for 3mA, but sterically excludes 7mG. Favorable π - π stacking interactions between the 3mA base and two aromatic side chains, rather than direct hydrogen bond interactions with the nucleobase, account for substrate specificity.

Human AAG

AAG, also known as MPG, is the human functional analog of AlkA and only known human BER DNA glycosylase that removes alkylation damage. It has a wide specificity range and removes other damage, similar to AlkA. AAG belongs to a distinct family of mammalian glycosylases characterized by a mixed α/β fold and no HhH motif. AAG is composed of a single α/β domain, with α -helices enclosing an antiparallel β -sheet (Figure 2(d)). AAG flips the alkylated nucleotide into a deep pocket, accompanied by side chain intercalation of β -hairpin residue Tyr162 into the DNA minor groove. Planar stacking and cation- π interactions by Tyr127, His136, and Tyr159 with the alkylbase account for substrate specificity. AAG excision specificity, like AlkA, likely depends on the chemical instability of positively charged, alkylated nucleobase glycosylic bonds. AAG bends substrate DNA by 20°, and widens the DNA minor groove by more than 2 Å. Although the active site can accommodate a variety of substrates, AAG uses a combination of nucleophilic activation/positioning and leaving group protonation for efficient alkylpurine catalysis. AAG simultaneously searches both DNA strands and bypasses DNA-bound protein roadblocks through hopping.

Prokaryotic HLR 3mA DNA Glycosylases (*B. cereus* AlkC and AlkD)

B. cereus AlkC and AlkD belong to a prokaryotic HLR 3mA DNA glycosylase superfamily. These enzymes contain no sequence homology to other known DNA glycosylases and likely catalyze nucleobase excision by a different mechanism. Both proteins efficiently excise 3mA. AlkC removes 3mG more efficiently than AlkD, whereas AlkD, but not AlkC, is proficient in excising 7mG. AlkD is a single α -helical domain protein, with 12 of its 14 helices arranged in antiparallel pairs to form six tandemly repeated Huntington/elongation/A subunit/target-of-rapamycin (HEAT)-like motifs that stack into a super-helical solenoid with a highly electropositive concave surface (Figure 2(e)). The concave surface contains a central shallow putative active site cleft of aromatic and charged residues. Stacking interactions between Trp109 and alkylated bases may be important for substrate recognition. An Asp113–Arg148 salt bridge is likely essential for alkylbase excision and may contribute to AlkD's specificity for positively charged alkylpurines. DNA was proposed to bind the concave surface in a novel mode of protein HEAT-repeat–DNA interaction, but no obvious DNA-intercalating side chains were identified. Surprisingly, AlkD DNA-binding models suggest that it may access the alkylbase for catalysis without flipping it into the aromatic cleft, raising the possibility of a different purpose for this cleft.

Repair of DNA-Alkylation Damage by Direct Damage Reversal Proteins

Repair of more stable DNA alkyl lesions, such as N1-substituted purines and O^6 -methylguanine, is accomplished by direct damage reversal proteins. These proteins reverse damage directly, without the need to break the DNA backbone, remove the damaged base, or further modify the nucleotide or DNA. DNA-alkylation direct damage reversal proteins fall into two categories: alkyltransferases and Fe(II)/2-oxoglutarate(2OG)-dependent dioxygenases.

Alkyltransferases

Alkyltransferases are widespread among prokaryotes and eukaryotes and repair O^6 -mG and O^4 -mT lesions. The N- and C-terminal domains of many prokaryotic alkyltransferases have distinct repair activities, as described later. For most eukaryotic alkyltransferases, the repair activity is completely

carried out by the C-terminal domain, whereas the N-terminal domain function is unknown. Alkyltransferase fusion proteins, such as *Caenorhabditis elegans* alkyltransferase-histone 1C and *Ferroplasma acidarmanus* alkyltransferase–endonuclease V, have also been identified.

N-Ada

E. coli contains two alkyltransferase proteins, the inducible Ada and the constitutively expressed Ogt. Ada is a multifunctional, two-domain protein, and each domain has a separate repair activity. The N-terminal domain of Ada (N-Ada) repairs Sp-methylphosphotriesters, but not Rp-methylphosphotriesters, via a zinc-activated Cys residue, resulting in covalent methylation of this domain. Methylated N-Ada has a significantly increased affinity for DNA and is thereby converted into an efficient transcriptional activator of several *E. coli* alkylation resistance genes within the *ada* regulon, including *alkA*, *alkB*, *aidB*, and *ada* itself. Thus, Ada is key to the *E. coli* adaptive response to alkylation damage.

N-Ada contains two subdomains, N-Ada_N and N-Ada_C, arranged along one face of the DNA helix and connected by a flexible linker (Figure 3(a)). N-Ada_C is an α -helical domain that binds the DNA major groove via a canonical helix–turn–helix (HTH) DNA-binding motif. N-Ada_N, a globular domain containing two α -helices enclosing a central β -sheet, contains zinc(II)-activated nucleophilic Cys38 and binds the DNA minor groove. To selectively recognize methylphosphotriester lesions and control its DNA-binding affinity and transcriptional regulation, N-Ada uses a methylation-dependent electrostatic switching mechanism whereby a negatively charged patch near the zinc–sulfur cluster at the protein–DNA interface is neutralized by a methylphosphotriester lesion or methylation of Cys38, thereby reducing charge–charge repulsion between the protein and the negatively charged DNA backbone and resulting in selective recognition of the neutral methylphosphotriester or enhanced DNA-binding affinity, respectively.

C-Ada, Ogt, and AGT

Two *E. coli* proteins, Ogt and the C-terminal domain of Ada (C-Ada), repair O^6 -mG and O^4 -mT. In higher eukaryotes and mammals, including humans, this repair is performed by O^6 -alkylguanine-DNA alkyltransferase (AGT), also known as hAGT or O^6 -methylguanine-DNA methyltransferase (MGMT) in humans. These proteins directly and covalently transfer the alkyl lesion from the damaged guanine to a conserved nucleophilic cysteine within a $-(I/V)PCHR(V/I)-$ active site motif in a stoichiometric, irreversible reaction. Alkylation damage can be

Figure 3 Crystal structures for direct damage reversal alkyltransferases. (a) *E. coli* N-Ada bound to DNA. Zn^{2+} is shown as a gray sphere. (b) *E. coli* C-Ada. (c) Human AGT bound to DNA. N-terminal domain (green), C-terminal domain (cyan), HTH motif (blue), base flipping residues (cyan sticks), and reactive Cys residue (yellow sticks) are shown.

repaired in ssDNA, but is preferentially repaired in dsDNA. C-Ada and other AGTs, including Ogt, can repair O^6 -alkylG lesions larger than methyl, but repair efficiency is affected by the alkyl group size. hAGT has a larger active site pocket than C-Ada and can more rapidly repair a broader range of bulky O^6 -alkylG lesions. The repair of O^4 -mT is most efficient in Ogt, followed by C-Ada, and finally hAGT, *in vitro*. However, *in vivo* reports of this repair are contradictory, and further studies are needed to clarify these inconsistencies. Interestingly, hAGT repair specificity and efficiency are altered by the modification of residues within and near the active site. In addition to preventing mutations, hAGT promotes tumor resistance to alkylating chemotherapies, making it a prime drug target.

The first of two C-Ada subdomains consists of two α -helices surrounding a β -sheet, whereas the second is mostly composed of α -helices and coils and contains conserved HTH and active site motifs (Figure 3(b)). hAGT is also a two-domain protein that shares C-Ada's α/β fold (Figure 3(c)). Like C-Ada, the hAGT C-terminal domain contains all known DNA-binding and alkyltransfer residues. For both C-Ada and hAGT, the reactive cysteine is in an interior cavity and activated for nucleophilic attack by a hydrogen bond network involving a histidine, glutamic acid, and structured water. hAGT binds the DNA minor groove via the HTH motif, flipping the alkylated guanine into its active site for repair. This nucleotide flipping is achieved by conserved arginine and tyrosine residues, with the arginine also stabilizing the extrahelical DNA conformation. AGT is a suicide protein because the alkyl adduct remains covalently attached and signals proteolytic degradation. AGTs likely detect DNA lesions by searching for weakened and/or distorted base pairs rather than the adduct. hAGT binds ss- and double-stranded (ds) DNA in a highly cooperative manner, which leads to a 3'-5' kinetic scanning bias aiding the search for damaged DNA through localization of multiple AGT molecules.

Fe(II)/2OG-Dependent Dioxygenases

Fe(II)/2OG-dependent dioxygenases are a large superfamily of proteins that catalyze a variety of biosynthetic and degradation reactions. DNA-alkylation damage is repaired by only certain family members, including *E. coli* AlkB, its human homologs ABH1, ABH2, ABH3, and the fat mass and obesity associated (FTO) dioxygenase. AlkB and its homologs repair 1mA and 3mC by coupling their oxidative demethylation to conversion of 2OG into succinate and CO_2 . The process requires iron(II), 2OG, and O_2 and the oxidized methyl group is spontaneously released as formaldehyde. Both AlkB and ABH3 prefer lesions in ssDNA and -RNA, whereas ABH2 preferentially repairs dsDNA lesions. AlkB also repairs 1mC, 3mT, 1, N^6 -ethenoadenine, 3, N^4 -ethenocytosine and analogs. ABH2 and ABH3 have a more narrow specificity, and ABH3 shows lower activity for 1, N^6 -ethenoadenine. FTO prefers 3mT in ssDNA or 3-methyluracil (3mU) in ssRNA. ABH1 has a very weak repair activity for 3mC in ssDNA and -RNA, but has stronger lyase activity for cleaving DNA at abasic sites.

AlkB, ABH2, and ABH3

AlkB, ABH2, and ABH3 have a core consisting of double-layered β -sheets in a jellyroll fold, matching other iron(II)/2OG-dependent dioxygenase superfamily members (Figures 4(a)–4(c)). The 2OG and iron cofactors are located near the conserved core H-X-D/E-Xn-H motif. AlkB has three extra β -strands that form a likely flexible nucleotide-recognition lid. Significant differences between AlkB and ABH3 include a more polar hABH3 substrate-binding cavity with key AlkB tryptophan replaced by tyrosine, structurally different DNA-binding interfaces, and different substrate-binding lid secondary structure suggesting distinct binding modes among AlkB homologs. Interestingly, ABH3 and ABH2 share some DNA-binding motifs, although substrate preferences differ. Notable AlkB and ABH2

Figure 4 Crystal structures for direct damage reversal dioxygenases. (a) *E. coli* AlkB bound to DNA and Mn^{2+} . (b) Human ABH2 bound to DNA and Mn^{2+} . DNA-intercalating Phe shown in cyan. (c) Human ABH3 bound to Fe^{2+} . (d) Human FTO bound to Fe^{2+} and 3mT (magenta sticks) showing N-terminal dioxygenase domain (green) and C-terminal domain (cyan). Mn^{2+} (gray sphere) and Fe^{2+} (orange sphere), 2OG (pink sticks), and flipped damaged base (magenta sticks) are shown.

DNA interaction differences include AlkB predominant contacts with the DNA damaged strand versus ABH2 significant interactions with both strands. Also, to achieve nucleotide rotation, AlkB pinches together the two bases on either side of the damaged base so that they stack with one another, whereas ABH2 intercalates an aromatic phenylalanine finger residue into the DNA.

FTO

FTO contains an AlkB-like domain and a second domain with a novel fold, both of which are necessary for catalytic activity (Figure 4(d)). One side of FTO's conserved jelly-roll motif is covered by an extra loop, not found in other AlkB family members. This loop competes with the nondamaged DNA strand for binding FTO, and likely plays an important role in maintaining ssDNA selectivity. Hydrogen-bond interactions between active site residues and the carbonyl oxygen atoms of 3mT or 3mU likely account for the substrate specificity of FTO.

Other Responses against DNA-Alkylation Damage

AidB

E. coli AidB is a part of the *ada* regulon of the *E. coli* adaptive response. Although AidB provides some cellular protection against S_N1 methylating agents, its exact function is unknown. AidB, related to the acyl-CoA dehydrogenase (ACAD) family of flavoproteins in sequence and fold, is a tetramer composed of a dimer of dimers, with the two FAD cofactors located at each of the dimer interfaces. Although the active site conserves many of the ACAD active site general features, notable differences include blocking and alteration of the putative substrate access channel environment by a conserved tryptophan and differences in the FAD cavity, suggesting it is not an active site for fatty or amino acid acyl-CoA thioesters. DNA is thought to bind in one of two places: an approximately 20-Å-wide, highly electropositive concave groove or near the positively charged substrate access channel mouth. The AidB tetramer ends bind DNA nonspecifically. Together, these observations suggest that AidB protects DNA by deactivating alkylating agents, rather than repairing it.

Lesion Bypass Polymerases

O^6 -mG lesions block the replicative DNA polymerases Pol α and Pol δ . However, bypass of these lesions by translesion synthesis (TLS) DNA polymerases may provide a means of survival in mammalian cells. DNA polymerase η can insert nucleotides opposite O^6 -mG *in vitro*, and other DNA polymerases, such as polymerase κ or polymerase ζ , may extend from an O^6 -mG:T mismatch, indicating that several TLS polymerases may be needed for O^6 -mG bypass. *In vivo* sensitivity to methylating agents is seen for cells defective in the polymerase ζ catalytic subunit, REV3, and further increased through inactivation of polymerase κ .

Mismatch Repair

The DNA MMR pathway repairs base substitution mismatches and small insertion or deletion mismatch loops formed during DNA replication. MMR also recognizes and attempts to repair O^6 -mG:T mispairs, but this repair leads to apoptosis. If MMR is

inactivated, O^6 -mG is highly mutagenic but not cytotoxic. The mechanism of how MMR leads to apoptosis is controversial. One long-held explanation is that MMR erroneously removes the thymine, and subsequent resynthesis by DNA polymerase restores the mispair. This leads to a futile cycle of nucleotide removal and synthesis, resulting in DNA single- and double-strand breaks and eventually apoptosis. Another proposal is that MMR complex binding to O^6 -mG:T mispairs directly signals apoptosis. Regardless of mechanism, it is likely that MMR proteins induce apoptosis by binding O^6 -mG:T mispairs and signaling their presence.

Alkyltransferase-Like Proteins and Connection to Nucleotide Excision Repair

The DNA nucleotide excision repair (NER) pathway repairs bulky, unrelated, helix-distorting lesions by excising a long DNA patch containing the lesion. Although NER can also repair O^6 -alkylG and O^4 -alkylT *in vitro*, its recognition of these nonbulky adducts is relatively poor. Alkyltransferase-like (ATL) proteins are AGT homologs that provide a connection for efficient O^6 -alkylG repair by NER (Figure 5). ATLs lack AGT's nucleophilic cysteine and are catalytically inactive, yet they protect cells against alkylation damage. ATLs tightly bind and promote repair of various O^6 -alkylG lesions, including many bulky lesions not repaired by AGTs. *S. pombe* and *Vibrio parahaemolyticus* ATLs retain the AGT C-terminal domain structural fold and conserve identities and roles of key DNA-binding and nucleotide flipping residues. ATL flips O^6 -alkylG into its binding pocket, analogous to hAGT, with the exception that here, nucleotide flipping is not connected to enzymatic activity. The ATL-induced 45° DNA bend, significantly more than the 30° DNA bend achieved by hAGT, is accompanied by an open-to-closed binding site loop conformational change, not seen for hAGT. Together, these observations suggest for ATL, nucleotide flipping is a switch for pathway activation rather than catalysis.

ATLs provide cellular protection by promoting a novel repair mechanism for O^6 -alkylG damage through cross-talk between DNA-alkylation base damage responses and NER, thereby linking two classically distinct DNA repair pathways. *In vitro*, *E. coli*, *S. pombe*, and *Thermus thermophilus* ATLs interact with NER proteins. An *in vivo* epistatic relationship has been shown for *S. pombe* and *E. coli* ATLs with *S. pombe* NER proteins Rad13 and Swi10 (homologs of human XPG and ERCC1) and *E. coli* NER protein UvrA, respectively, establishing ATL's connection to NER. In organisms where AGT and ATL coexist, such as *E. coli*, O^6 -alkylG adducts are repaired by the AGT or NER pathways according to their size, leading to a proposed enhanced-NER pathway, where ATL mediates bulky O^6 -alkylG repair by NER, whereas AGT repairs O^6 -mG (Figure 5). Although most known ATLs are bacterial or yeast, ATLs have recently been discovered in archaea and the multicellular starlet sea anemone *Nematostella vectensis*, showing that ATLs exist in all three domains of life.

Conclusion

DNA-alkylation damage, prevalent within cells, can have detrimental cellular effects if left unrepaired. Cells use a vast

Figure 5 ATL binds O^6 -alkylG to direct its repair into the NER pathway. If AGT and ATL coexist, ATL and AGT compete for O^6 -alkylG repair. ATL apo (open) and DNA-bound (closed) structures show the nonenzymatic nucleotide flip switch that signals repair by NER.

number of DNA repair mechanisms to protect them from these potentially lethal effects. These include the main dealkylation mechanisms of BER and direct damage reversal, and the recently discovered ATL protein-mediated channeling of alkylation damage away from classical base responses and into NER. The significant threat to genomic stability posed by DNA alkyl lesions is reflected in their extensive and creative repair mechanisms within the cell.

Glossary

Abasic or apurinic/aprimidinic site A deoxyribose residue in DNA that lacks a nucleobase.

DNA glycosylase Enzymes that recognize and remove damaged (chemically altered) bases from DNA.

N-Glycosylic bond The bond connecting the anomeric carbon of the deoxyribose to the nitrogen of the purine or pyrimidine base.

Nucleotide flipping The process by which an enzyme extrudes a nucleotide from the DNA helix into the active site (also known as base flipping).

Transition state The state of most positive Gibbs free energy through which reactants must pass during the transformation to products. The difference in free energy between the reactants (ground state) and the transition state, termed the activation barrier, determines the rate of a reaction.

Introduction

DNA glycosylases recognize and remove damaged bases in DNA and are essential for maintaining genomic integrity, and some glycosylases play an important role in transcriptional regulation and the immune system. The four nucleobases of DNA are reactive and subject to continuous chemical modification, giving a large variety of lesions resulting from alkylation (i.e., 3-methyladenine), oxidation (8-oxoguanine), deamination (cytosine to uracil), and ultraviolet (UV) radiation (pyrimidine dimers). These lesions can be mutagenic, due to miscoding properties during DNA replication, and/or cytotoxic, because they can block DNA or RNA polymerases. Damage to individual bases in DNA is handled by the base excision repair (BER) pathway, one of the several DNA repair systems found in all forms of life.

We can think of BER in terms of two basic phases – recognition and excision of the altered base by a damage-specific DNA glycosylase, and subsequent steps that replace the damaged nucleotide using the undamaged strand as a template. DNA glycosylases use a remarkable nucleotide-flipping mechanism to extrude damaged nucleotides from the DNA helix into their active site, where they cleave the base-sugar (*N*-glycosylic) bond to release the damaged base. All organisms are armed with many different DNA glycosylases (11 are found in human cells), some of which are highly specific for a single lesion, while others can remove a broad range of lesions.

In addition to handling spontaneous DNA damage, some DNA glycosylases are required for other important cellular processes. Uracil DNA glycosylase (UNG) contributes to the acquired immune response by excising uracils created in antibody genes (by active cytidine deaminase), leading to antibody diversity through somatic hypermutation or class-switch recombination. In addition, replication of retroviruses and retrotransposons is inhibited by degradation of reverse transcripts via cytidine deamination and UNG-mediated uracil excision. In plants, DNA glycosylases mediate gene imprinting by excising 5-methylcytosine (m^5C), a modified base that signals for transcriptional silencing. Two DNA glycosylases appear to

participate in transcriptional regulation in mammals, thymine DNA glycosylase (TDG) and methyl binding domain IV (MBD4), although their role likely involves excision of T from G-T mismatches created by active m^5C deamination rather than excision of m^5C directly.

Types of DNA Glycosylases

DNA glycosylases are classified as either monofunctional, which have base-excision (glycosylase) activity only, or bifunctional, which also have DNA lyase activity (Figure 1). The mechanism of the glycosylase reaction and subsequent steps of the BER pathway differs substantially for these two types of enzymes. Monofunctional enzymes cleave the glycosylic bond by catalyzing a reaction in which water is the nucleophile, producing a common product, an apurinic/aprimidinic (AP) or abasic site in the DNA. This mutagenic and toxic BER intermediate is recognized and processed by an AP endonuclease, which hydrolytically cleaves the 5'-phosphodiester bond at the AP site. AP endonucleases yield a 3'-OH primer for repair synthesis, and other BER enzymes complete the repair process. Bifunctional enzymes excise damaged bases by catalyzing a glycosyl transfer reaction, where the nucleophile is an amine provided by the enzyme (Lys side chain or the amino terminus of the protein). The resulting Schiff base intermediate undergoes β -elimination, promoted by the lyase activity, cleaving the C3'-O bond of the damaged nucleotide. The remaining portion of the damaged nucleotide is recognized and removed by an AP endonuclease, leaving a 3'-OH primer for repair synthesis. Some bifunctional enzymes also catalyze a δ -elimination reaction that cleaves the C5'-O bond, which completely excises the damaged nucleotide. Following β - or β/δ -elimination, downstream BER proteins complete the repair process.

DNA glycosylases can be categorized according to overall fold into one of six superfamilies, some of which contain many enzymes that together recognize a very broad range of lesions. The helix-hairpin-helix (HhH, or Endo III) superfamily is a large and diverse collection of mono- and bifunctional enzymes that is represented by *Escherichia coli* enzymes MutY

Figure 1 DNA glycosylases recognize and remove damaged bases by cleaving the base-sugar (*N*-glycosylic) bond. Monofunctional DNA glycosylases catalyze a hydrolytic reaction (water is the nucleophile) and produce an abasic (or AP) site, and downstream enzymes complete the repair process. Bifunctional enzymes cleave the glycosidic bond using an amine as the nucleophile (Lys side chain or amino terminus of protein), giving a Schiff base intermediate. The bifunctional enzymes also have lyase activity, and can cleave the DNA backbone 3' to the lesion (β -elimination) or 3' and 5' to the lesion (β,δ -elimination). Downstream BER enzymes restore the correct nucleotide.

(this removes adenine from A-8-oxoG pairs) and the alkylation damage-repair enzymes AlkA and TAG, and eukaryotic 8-oxoguanine glycosylase (OGG1). The helix-two-turn-helix (H2TH) superfamily includes bifunctional enzymes that handle oxidized bases, the MutM and Nei glycosylases. The UNG superfamily includes many monofunctional enzymes, some of which can remove a variety of uracil analogs and other modified pyrimidines. The alkyladenine DNA glycosylase (AAG) family of monofunctional enzymes, represented by human AAG, handles a broad range of lesions. The HEAT-like repeat (HLR) superfamily, including AlkC and AlkD, removes positively charged methylpurines and is found in prokaryotes and lower eukaryotes. The sixth superfamily, pyrimidine dimer glycosylases (PDGs), are bifunctional enzymes that mediate excision of cyclobutane pyrimidine dimers, and is best represented by the Endo V enzyme from bacteriophage T4.

Nucleotide Flipping: A Universal Trait

DNA glycosylases are charged with the daunting task of finding and removing damaged bases within the huge (million-fold) excess of undamaged DNA. Often, the lesion differs only slightly from the undamaged base and does not substantially perturb the overall DNA structure, complicating the search process. To overcome this problem, DNA glycosylases extrude the damaged nucleotide from the helix into an active site, a reversible step called nucleotide flipping (or base flipping) that precedes cleavage of the glycosylic bond (Figure 2). Nucleotide

flipping allows glycosylases to form interactions required for lesion recognition, provides access to the scissile C–N bond, and places the lesion in an active site with a chemical environment that promotes catalysis. The conformational change is quite large, as the target nucleotide is rotated by up to 180° out of the DNA helix. The finding that all glycosylases employ nucleotide flipping reflects the importance of this step in the enzymatic reaction, which couples lesion recognition and base excision. Nucleotide flipping is also used by other enzymes such as alkylguanine transferases that modify DNA and RNA, and it was first observed for a cytosine methyltransferase.

DNA glycosylases use several approaches to promote nucleotide flipping, which is energetically costly due to disruption of base pairing and stacking interactions and unfavorable DNA backbone conformational changes. Glycosylases typically interact with two or three phosphodiester groups on each side of the target nucleotide, and some enzymes contact phosphodiester groups in the complementary DNA strand. These contacts enable sequence-independent DNA binding, allow for rapid DNA scanning, and provide a scaffold for enzymatic distortion of the DNA to promote and/or stabilize nucleotide flipping. Structures of glycosylases bound to DNA, with a target lesion flipped into the active site, reveal that nucleotide flipping involves bending of the DNA helix at the lesion site. The degree of bending, and the point along the nucleotide-flipping pathway at which it occurs, depends on the glycosylase. Although our understanding of exactly how DNA bending facilitates nucleotide flipping remains incomplete, computational studies indicate that DNA bending lowers the energetic barrier to

Figure 2 DNA glycosylases use a remarkable process known as nucleotide flipping (also called base flipping) to extrude nucleotides from the helix into their active site, where the glycosidic bond is cleaved. Shown is the crystal structure of MutY (*Bacillus stearothermophilus*) with the target nucleotide (dA, red) flipped into its active site (PDB ID: 3G0Q). MutY also recognizes the 8-oxoguanine (blue) that has been base-paired with the target dA in the DNA helix. Recognition of 8-oxoG, which remains stacked in the helix, is important for avoiding enzymatic excision of adenine from the million-fold excess of A-T base pairs. The figure was generated by Pymol, and the structure was solved by Lee and Verdine. From Lee S and Verdine GL (2009) Atomic substitution reveals the structural basis for substrate adenine recognition and removal by adenine DNA glycosylase. *Proceedings of the National Academy of Sciences of the United States of America* 106: 18497–18502.

nucleotide flipping. Glycosylases also promote and/or stabilize nucleotide flipping by inserting one or more amino acid side chains into the DNA helix. For example, most glycosylases fill the helical space vacated by the flipped nucleotide using a bulky side chain (Asn, Arg, Gln, Leu, or Tyr). Some insert a wedge between bases in the complementary DNA strand, typically adjacent to the base that is paired with the target nucleotide. Finally, many glycosylases form selective steric and/or electrostatic interactions with the target lesion in the active site, which stabilize nucleotide flipping and can trigger a conformational change that positions active-site residues for catalysis. Thus, most glycosylases promote nucleotide flipping by bending the DNA, plugging the helical space vacated by the flipped nucleotide, and/or retaining the lesion in the active site.

While some glycosylases appear to initiate nucleotide flipping by selectively disrupting base-pairing interactions to push target nucleotides out of the helix, other glycosylases simply trap nucleotides that spontaneously flip due to normal breathing of the DNA base pairs. Nuclear magnetic resonance and crystallographic studies show that UNG uses a passive trapping mechanism to find dU lesions in DNA. UNG traps dU and dT nucleotides that flip spontaneously from the DNA helix into an 'exo-site' that is distinct from the active site. The exo-site lies along the nucleotide-flipping pathway and interacts transiently with dU and dT nucleotides that have flipped $\sim 40^\circ$ out of the helix. UNG does not alter the rate at which dT or dU nucleotides flip out of the helix; rather, it slows the rate at which they flip back into the helix. However, dT does not flip stably into the UNG active site due to steric clashes with its C5-methyl group (dU has a hydrogen at C5). The exceedingly short

lifetime for the open state of an A·U base pair ($<0.1 \mu\text{s}$) indicates that UNG cannot simply bind dU nucleotides that have already flipped. Kinetics experiments show that the residence time of UNG at any given site in DNA ($\sim 0.5 \text{ ms}$) is long enough to encounter many spontaneous flipping events.

OGG1 has an exo-site that interacts transiently with extrahelical dG and oxo-dG nucleotides, but only oxo-dG flips fully into the active site. Single-molecule studies of OGG1 indicate that it slides along the DNA at a very rapid rate, sampling hundreds of base pairs before dissociating, and its residence time at any given site appears too short to trap oxo-dG nucleotides that flip spontaneously from DNA. This suggests that OGG1 selectively promotes the flipping of oxo-dG nucleotides, because a mechanism whereby all dG residues were flipped into the exo-site would be too time consuming to account for the observed rapid sliding on DNA. The process of searching for oxo-dG lesions is more fully understood for the MutM glycosylase, which also slides rapidly along the DNA. Structural studies indicate that MutM interrogates DNA using a process that involves DNA bending and selective distortion of oxo-G·C base pairs to promote flipping of oxo-dG lesions.

The Catalytic Mechanism of DNA Glycosylases

The *N*-glycosidic bond is quite stable for the four normal nucleotides in DNA, and most damaged nucleotides, and glycosylases employ a number of strategies to meet the significant catalytic challenge of cleaving this bond. The spontaneous hydrolysis of 2'-deoxynucleosides is exceedingly slow, and occurs with a half-life ranging from 12 years for dG to 43 years for dC, at pH 7 and 37°C . The nucleotides are even more stable in duplex DNA, where spontaneous hydrolysis occurs with a half-life of 400 and 11 000 years for purines and pyrimidines, respectively, suggesting that glycosylases attain some degree of catalysis by simply flipping the target nucleotide into their active site. DNA glycosylases increase the rate of glycosidic bond cleavage by 10^{12} -fold compared to the corresponding nonenzymatic reaction. We first consider the mechanism of enzymatic and noncatalyzed reactions, and then discuss how glycosylases catalyze these reactions.

Noncatalyzed *N*-glycosyl hydrolyses and *N*-glycosyl transfer reactions follow a stepwise or a highly dissociative mechanism, where rupture of the glycosidic bond fully precedes or is greatly advanced over the nucleophile approach (Figure 3). The transition state (TS) involves positive charge on the sugar and migration of negative charge into the departing base. The detailed reaction mechanism has been determined for two DNA glycosylases, UNG and MutY, both monofunctional enzymes (water is the nucleophile). The UNG reaction is stepwise, where cleavage of the glycosidic bond in the first TS gives a short-lived oxacarbenium ion–uracil anion intermediate, and water attacks the cationic sugar in the second TS (Figure 1). The reaction catalyzed by MutY is also stepwise, but the glycosidic bond breaks and re-forms many times before nucleophilic attack, which is the first irreversible step. Remarkably, this indicates that the most probable event following glycosidic bond cleavage is re-formation of the bond and dissociation of MutY from DNA substrate.

DNA glycosylases use one or more of three basic strategies to catalyze the excision of damaged bases from DNA in a timely

Figure 3 Two potential mechanisms for 2'-deoxynucleoside hydrolysis. A stepwise reaction (S_N1, upper pathway) has two transition states, one for C–N bond cleavage and one for nucleophile (water) addition, separated by a short-lived oxacarbenium ion intermediate. Hydrolysis of 2'-deoxynucleosides can also follow a highly dissociative mechanism (S_N2, lower pathway), where glycosidic bond cleavage is greatly advanced over nucleophile approach, and significant positive charge develops on the sugar in the transition state (TS). A stepwise mechanism is observed for nonenzymatic dAMP hydrolysis, and for enzymatic hydrolysis of dU in DNA by UNG and of dA in DNA by MutY and ricin. For the MutY reaction, the glycosidic bond is cleaved and reformed many times before water is added in the first irreversible step. In contrast, for UNG, the first irreversible step is likely C–N bond cleavage. While MutY protonates the adenine base prior to glycosidic bond cleavage, which activates it for departure, UNG does not protonate the uracil base, which departs as an anion (as indicated above).

manner to preserve genomic integrity. These include (1) stabilization of unfavorable positive charge that develops on the sugar and negative charge that develops on the departing base, (2) protonation of the base to activate it for departure (general acid catalysis, particularly for purines), and (3) orientation and/or activation (via deprotonation) of the nucleophile to promote attack of the anomeric carbon.

Cleavage of the glycosidic bond involves transfer of electrons into the nucleobase, which is unfavorable because the anionic base is a poor leaving group and a good nucleophile. DNA glycosylases can enhance the leaving ability of the base by protonation (general acid catalysis), which activates it for departure because the protonated base is electron poor. Alternatively, glycosylases can stabilize the negative charge that develops on the base in the TS (electrostatic catalysis). Detailed studies of the UNG reaction show that the uracil base departs as an anion, which is stabilized by a strong hydrogen bond provided by a conserved His side chain (to uracil O2). It is likely that excision of uracil or thymine by other glycosylases involves departure of the pyrimidine anion. In contrast, MutY catalyzes cleavage of dA nucleotides by transferring a proton to adenine N7 prior to bond cleavage, activating the adenine base for departure. Some alkylated bases carry a positive charge (are electron deficient) and are good leaving groups in the absence of enzyme activation, a feature that can be used by glycosylases to distinguish the alkylated base from its undamaged counterpart.

DNA glycosylases also attain substantial rate enhancement by stabilizing the glycosyl cation that develops in the TSs of the reaction. UNG stabilizes the oxacarbenium ion using a constellation of proximal anionic groups, including a conserved Asp side chain, phosphates of the DNA backbone, and the departing anionic uracil base. The observation that many glycosylases

bind more tightly to DNA containing a positively charged mimic of the oxacarbenium ion TS than to DNA containing a neutral mimic of the abasic site product suggests that they stabilize the glycosyl cation in a manner similar to UNG. However, unlike UNG, many glycosylases do not have a carboxylate side chain to stabilize the glycosyl cation, and for many glycosylases, the base departs in its neutral rather than anionic form. Thus, some glycosylases may stabilize the cationic sugar using primarily backbone phosphates, and some may stabilize TS by other means, including activation of the leaving group or the nucleophile.

Another strategy for TS stabilization for many DNA glycosylases is activation and/or positioning of the nucleophile for attack at the anomeric carbon (C1'). Many glycosylases have a conserved Asp or Glu side chain that can abstract a proton to activate the nucleophile (general base catalysis) or at least orient the nucleophile for attack. Some glycosylases have an Asn in the corresponding position, which can orient but not activate the nucleophile. The observation that many glycosylases have a nonpolar side chain at this position (i.e., Ala or Gly) indicates that the nucleophile can be activated by other means or that nucleophile activation is not needed for these glycosylases. Consistent with this conclusion are findings that for some glycosylases, substitution of the conserved Asp or Glu residue does not dramatically alter catalytic activity.

How Do DNA Glycosylases Attain Specificity?

DNA glycosylases use a number of approaches to meet the formidable task of finding and removing lesions while avoiding the million-fold excess of normal DNA. While some DNA

glycosylases are specific for one type of base damage, others are permissive and can remove a broad range of lesions. For many glycosylases, the active site is sterically restrictive and provides electrostatic interactions that select for the cognate lesion, excluding other lesions and undamaged DNA. UNG is highly specific for removing uracil from DNA; its active site sterically rejects adenine, guanine, and thymine, and it forms hydrogen bonds with uracil that are not compatible with cytosine. UNG rapidly excises uracil but cannot remove thymine due to steric hindrance of the CH₃ at C5 of thymine (uracil has a hydrogen at C5). In addition, some glycosylases exhibit strong specificity not only for a particular target nucleotide, but also for its base-pairing partner in the complementary strand. MutY is highly specific for removing adenine when it is base-paired with 8-oxoguanine (A-oxoG), but does not remove adenine from normal A-T pairs. The active site of prokaryotic TAG enzymes is highly specific for the excision of 3-methyladenine.

Given the limiting number of DNA glycosylases and the much larger number of potential lesions, some glycosylases must handle multiple types of damage. Not surprisingly, these enzymes have a relatively permissive active site and typically provide few selective interactions with their various target bases. For example, *E. coli* AlkA removes a broad range of purines and pyrimidine lesions arising predominantly not only from alkylation but also from deamination and oxidation, and AlkA can remove undamaged bases, albeit at a greatly reduced rate. The specificity of AlkA stems in part from certain properties of the damaged base. For example, alkylated bases carry a positive charge and are pre-activated for departure, such that the glycosylic bond is more readily cleaved. In addition, some damaged bases exhibit impaired hydrogen bonding and/or stacking interactions and are prone to be extrahelical, which promotes tighter binding to AlkA and faster base excision. Similar observations were made for human AAG, which removes a range of lesions, mostly alkylpurines and some deaminated purines such as hypoxanthine.

Some glycosylases with a permissive active site exhibit strong specificity for the base-pairing partner of the target nucleotide. Members of the TDG–mismatch uracil glycosylase (MUG) family, represented by human TDG and *E. coli* MUG, remove a variety of lesions and exhibit strong specificity for excising bases paired with guanine rather than adenine, which is consistent with findings that G-U or G-T mispairs are their predominant biological substrate. Given the strong specificity of TDG–MUG enzymes for removing bases paired with G, they

must employ a stringent mechanism to avoid excision of cytosine from normal G-C pairs. The broad substrate range of TDG, which includes modified cytosines, indicates that the specificity does not involve selective substrate interactions that exclude cytosine from the active site. Instead, specificity of TDG for G-T over G-C pairs arises largely at the chemical step of the reaction, where the scissile *N*-glycosylic bond is much more readily cleaved for dT relative to dC. Other glycosylases with an indiscriminate active site attain specificity at the chemical step. AlkA removes many lesions with a rate that depends on *N*-glycosylic bond stability.

Glossary

Dissociation constant (K_d) Measures the affinity between enzyme and its substrate. It has molar (M) unit, and smaller the number, tighter the binding/affinity.

Holliday junction A four-stranded DNA structure that is an intermediate in DNA recombination.

Introduction

Since its discovery in 1976 from *Escherichia coli*, we have come a long way in understanding helicases. It is now clearer than ever that these nucleic acid (NA) motor proteins are found ubiquitously and helicases alone constitute approximately 2% of all encoded proteins in eukaryotes. Helicases use the energy of nucleoside triphosphate (NTP) hydrolysis to perform an array of NA (RNA or DNA)-related functions including translocating on single-stranded (ss) and double-stranded (ds) NA, separation of the dsDNA strands, removal of the secondary structures in RNA, displacing proteins bound to NAs, remodeling chromatin, and moving the Holliday junction. Given the pivotal role played by helicases in NA metabolism, it is not surprising that, mutations in human genes coding for helicases are associated with premature aging and various types of cancers. In viruses, helicases play a key role in genome replication and its packaging/unpackaging. Hence, viral helicases are prospective targets for developing antiviral therapy. The topic of helicase structure, function, and mechanisms has been widely discussed in the existing literature. This review focuses primarily on the structure and mechanisms of ring-shaped hexameric helicases.

Ring-shaped helicases are found across all species, from bacteria to humans (Table 1). The most commonly studied ring-shaped helicases are DnaB, RepA, and Rho of the *E. coli*, T7 gp4, G40P, and T4 gp41 of bacteriophages, SV40 large T antigen and E1 of eukaryotic viruses, minichromosome maintenance (MCM) 2–7 in eukaryotes and mitochondrial helicase TWINKLE in humans. Hexameric helicases can broadly be divided into two types based on their conserved adenosine triphosphatase (ATPase) core, namely, RecA and AAA⁺. Most of the RecA-type helicases move in the 5′–3′ direction on ssNA, while the AAA⁺-type helicases move in the 3′–5′ direction.

Hexameric Helicase Structure with ssNA

The uniqueness of hexameric helicases lies in their structure. Structural studies show that the six subunits are arranged like a toroid with an outer diameter of ~120 Å, and a ~80-Å-long central channel with a diameter of ~20 Å (Figure 1). This three-dimensional structure of the hexameric helicase is conserved across bacteriophage, viruses, prokaryotes, and eukaryotes.

Most ring-shaped helicases are homo-hexamers, except for the eukaryotic MCM helicases, that assemble into a hetero-hexamer of MCM2–7 proteins. Biochemical and electron microscopy data have indicated that the NA binds in the central channel. The crystal structures of *E. coli* Rho and papilloma virus E1 (with 379 amino acids deleted from its N-terminal domain) helicases provided the first glimpse of the interactions of the ssNA within the central channel (Figure 1). The structures of Rho (with adenosine diphosphate.beryllium fluoride (ADP.BeF₃)) and E1 (with ADP) show five subunits of the six interacting with five nucleotides of ssNA – each subunit interacting with one nucleotide of ssNA. Two loops from each subunit protrude into the central channel forming a ‘spiral staircase’-like structure to interact with the sugar–phosphate backbone of the NA explaining the sequence-independent binding of helicases to ssNA. Despite their structural differences and opposite directionality of translocation – E1 being an AAA⁺ family of 3′–5′ helicase and the Rho being a Rec A family of 5′–3′ helicase – both bind ssNA with the same polarity. The 5′ end of the ssNA (top of the staircase) is proximal to the N-terminal domain of both the helicases. Structures suggest that Rho and E1 fire adenosine triphosphate (ATP) in opposite sequence of directions around the ring to drive NA translocation in opposite directions.

Loading of the Ring-Shaped Helicases on the NA

The annular conformation of hexameric helicases raise an obvious question: How does the NA enter the central channel? Odds are probably low under *in vivo* conditions (although possible *in vitro*) for the NA threading itself into the central channel like a thread through a needle. Most ring-shaped helicases rely on proteins called the loaders to help it encircle NA (Table 1). A loader is either a separate protein that interacts with its corresponding helicase and with the NA (e.g., DnaC for DnaB helicase in *E. coli*) or helicase’s own specific domain endowed with the loading task (e.g., primase domain in T7 gp4 protein and N-terminal RNA-binding domain in Rho).

These proteins help to load the helicase on the NA by acting either as ring breakers or as ring makers. Helicases with low K_d for hexamerization are stable rings without the NA. In this case, the loader needs to break the ring either by completely disassembling the ring or, more likely, by creating openings between the subunits to get the NA into the central hole.

Table 1 RecA and AAA⁺ ring-shaped helicases

Protein fold	Name	Polarity	Function	Loader
RecA	Bacterial DNAB	5'–3'	DNA unwinding	DNAC
	Phage T7 gp4	5'–3'	DNA replication	N-terminal primase domain
	Phage T4 gp41	5'–3'	DNA unwinding	gp59
	G40P	5'–3'	DNA unwinding	G39P
	Bacterial Rho	5'–3'	RNA–DNA heteroduplex unwinding and transcription termination	N-terminal domain
	Human mitochondrial TWINKLE	5'–3'	DNA unwinding	?
	Φ 12 P4	5'–3'	ssRNA packaging	?
AAA ⁺	pRSF1010RepA	5'–3'	DNA unwinding	?
	Papilloma virus E1	3'–5'	DNA unwinding	E2
	Simian virus 40 Large T-antigen	3'–5'	DNA unwinding	Loads on its own. Loader domain?
	Eukaryotic or archaeal MCMs	3'–5'	DNA unwinding	Cdc6–Cdt1 in <i>S. cerevisiae</i>
	Bacterial RuvB	dsDNA	Resolving Holliday junctions	RuvA

For helicases that are not stable hexamers, the loader actually builds the ring by putting the monomeric subunits together around the NA.

ATP binding/hydrolysis by the loaders is believed to play a crucial part in loading of hexameric helicases. When a separate protein acts as a loader, the loaders are ATPases, for example, Cdc18 of *Saccharomyces pombe* Mcm2-7 is an AAA⁺ ATPase, Cdc6 of *S. cerevisiae* Mcm2-7 requires ATP hydrolysis for loading, and DnaC for *E. coli* DnaB is an ATPase. Where two separate loaders are involved, at least one performs ATP hydrolysis; for example, DnaI for *Bacillus subtilis* DnaC is an ATPase only in the presence of another loader DnaB and this ATPase activity is further stimulated in the presence of ssDNA, but DnaI does not hydrolyze ATP in the absence of DnaB. However, for helicases with a domain of its own acting as a loader, ATP hydrolysis is not required for loading. For example, the N-terminal domain of Rho does not show any ATP-binding motif. For phage T7 gp4, the presence of deoxythymidine triphosphate (dTTP), but not its hydrolysis, is required for hexamer assembly around the DNA. Hence, the role of ATPase might be as a gatekeeper at the transition of loading and unwinding.

The protein loaders interact directly with NA in addition to their substrate helicase. This interaction has been reported in loaders such as DnaB, the co-loader for *B. subtilis* DnaC, DnaC the loader for DnaB in *E. coli*, gp59 loader for phage T4 gp41 helicase, Cdc6 loader for *S. cerevisiae* MCM 2–7, primase domain of phage T7 gp4, and RNA-binding domain of Rho, to mention a few. There is no information available for heterologous loader loading a helicase; hence, it is reasonable to assume that the interaction between loader and its corresponding helicase is extremely specific. For example, DnaC in *E. coli* binds the N-terminal domain of DnaB helicase.

After loading is completed, the helicase does not lug the loader along during unwinding. For example, DnaC loader for DnaB helicase in *E. coli* simply acts as a loader and gatekeeper between loading and unwinding steps and dissociates after loading. Similarly, Cdc6–Cdt1 dissociate from Mcm2–7 in *S. cerevisiae* after loading by hydrolyzing ATP.

The scenario in the cell is more complex than *in vitro* conditions for loading, in which forked junctions or single-stranded loading conformations are not readily available in the genome. Therefore, in addition to the loader, accessory

proteins (initiators) are required for origin remodeling and setting the stage for helicase loading and unwinding. Even though the complexity of genome of bacteria and yeast is incomparable, it has been observed that the accessory proteins for both function in a similar manner; they form the origin recognition complex at the origin, open up the duplex NA to form an ss bubble-like structure, followed by turning on the loader that loads the helicase at the origin to form the prereplicative complex, finally loading the polymerase and primase leading to replication. It is possible that the same mechanism could be extrapolated to metazoans as well.

Even when ss structures are available in the genome at regions of accidental replication fork arrest, the loading of helicase is regulated by specific proteins that form complexes at the site and attract the helicase and its loader. An example for this mechanism can be seen in *E. coli*, where the primosome complex (PriA, PriB, PriC, and DnaT) attracts DnaC–DnaB to the site of replication fork arrest.

The complexity of loading of hexameric helicases on NA has begun to be unveiled by biochemical and structural studies. Future probably lies in visualizing the dynamics of these events by a congruence of single-molecule and *in vivo*-imaging techniques.

Mechanisms of NTPase-Powered Translocation of Ring Helicases

Loading of the helicase is followed by its translocation on NA, which is fueled by NTP hydrolysis. The RecA or AAA⁺-like NTPase core binds and hydrolyzes NTP to nucleoside diphosphate (NDP) and inorganic phosphate (Pi) in the presence of the essential cofactor Mg²⁺. Most helicases use ATP as the substrate, unlike others such as T7 gp4 which has a specific requirement for dTTP. The first glimpse of the NTPase active site was obtained from the crystal structure of the T7 gp4 without any bound NA. This structure showed that the NTPase active sites are located at the subunit interfaces, currently recognized as a general feature of hexameric helicases. Amino acids from adjacent subunits participate in NTP binding and hydrolysis. The Walker A and B motifs from one subunit cooperate with the arginine finger from its neighboring subunit to bind

Figure 1 Structures of *E. coli* Rho and BPV E1 helicases demonstrating the structural similarity among two classes of hexameric helicases RecA and AAA⁺: (a) and (b) represent the top views of Rho (3ICE) and $\Delta 379$ E1 (2GXA), respectively. The six subunits of the hexamer assume a toroidal shape with a central channel accommodating the ssNA. A single chain of the hexamer is highlighted (yellow) to show the two loops, which forms a staircase-like structure that interacts with ssNA (brown) in the central channel. The cyan spheres represent the ADP•BeF₃ (in orange) in Rho and ADP in E1. The Arginine finger is the yellow stick interacting with the Walker B motif of the adjacent chain. (c) and (d) represent the side views of Rho and E1, respectively, with the N-terminal domain to the left and C-terminal domain to the right. The brown strand represents the ssNA in the central.

NTP and catalyze its hydrolysis (Figure 1). This interfacial mode of NTP binding provided the initial model for the structural basis for the intersubunit transmission of the changes rooting from NTP binding and hydrolysis to DNA-binding/unbinding reactions in the ring. Biochemical studies have shown that the hexamer binds NTP, NTP analogs (nucleoside 5'-(β,γ -imido) triphosphate (NMPPNP), nucleoside (β,γ , methylene) triphosphate (NMPPCP), NDP.BeF₃), and NDP with micromolar K_d values and stoichiometry of 4–6 NTPs/hexamer.

The NA affinity of the hexameric helicase depends on its nucleotide-ligation state. For example, T7 gp4 binds ssDNA tightly in the presence of dTTP without Mg²⁺, an essential cofactor for NTPase. This binding is unaffected if dTTP is replaced by its nonhydrolyzable analog deoxythymidine (β,γ , methylene) (dTTP-PCP), but becomes 500 times weaker in the presence of deoxythymidine diphosphate (dTDP). Similar observation was recorded with the DnaB helicase that binds ssDNA with 200-fold tighter affinity with adenylyl-imidodiphosphate

(AMP.PNP) as compared to ADP. From these observations, it was proposed that NTP binding and Pi release promote DNA binding and release events, respectively. The exact sequence of ATP hydrolysis around the ring, which brings about NA binding and unbinding, is not known.

Mutant poisoning experiments indicated that one or two inactive mutant subunits in the ring can inactivate the helicase. This ruled out a mechanism whereby NTPs are hydrolyzed randomly and suggested a mechanism whereby NTP hydrolysis is coordinated among the six subunits. Initial presteady-state dTTPase studies in the absence of DNA suggested that three out of the six sites of T7 gp4 were active, similar to the F1-ATPase. Presteady-state NTPase kinetics experiments of Rho and T7 gp4 with ssNA showed hydrolysis of more than three NTPs. These results suggested the involvement of all six subunits of the hexameric helicase in catalysis. Although, there is a general agreement that the NTPase reactions are coordinated among the subunits of the ring, it is not known if the sequence of events, ATP binding, hydrolysis, and product release, resulting in NA movement is conserved across helicases.

Based on presteady-state NTPase studies and protein–DNA cross-linking data of T7 gp4 that indicated binding of one to two subunits to ssNA at any time, a 2-site sequential mechanism was proposed wherein two subunits were proposed to be involved in the ssNA binding–unbinding coupled to ATP binding and hydrolysis in the following manner (Figure 2): upon binding NTP, a subunit makes tight interactions with the NA, and upon NTP hydrolysis the subunit loses its grip on the NA. The complete release of the NA is prevented by the cooperative action of two adjacent subunits. Before the NA is completely released by a subunit, the neighboring subunit assumes the NTP-liganded state and binds the NA at a forward position resulting in processive translocation of the NA. Hence, at any given point of time, only two of the six subunits are actively playing a role in NTPase-coordinated translocation.

Figure 2 Models of single-stranded nucleic acid translocation by hexameric helicase. The star (blue) represents the hexamer with the inner core (central channel) exposed out. The inner NA-binding loops and the NTP-binding domains of the hexamer are splayed open to clearly show the interaction of the NA with each domain. The red strand represents NA and each subunit of the hexamer is represented as individual triangles in the star. The 2-site model postulates that at any time two subunits interact with the NA and during translocation if subunit-1 is unbinding NA, the subunit-3 is binding NA. The 5-site coordinated escort model postulates that any time five subunits interact with the NA, and during translocation as subunit-1 is unbinding NA, subunit-6 is binding NA.

An alternative coordinated escort model was proposed from a snapshot provided by the crystal structures of E1 and Rho helicases that showed that ssNA was bound to five subunits of the ring (Figure 2). The major difference between the 2-site sequential and coordinated escort model is two versus five subunits bound to ssNA at any time. However, both the models agree that while one subunit is binding NA another one is unbinding from the NA.

According to the coordinated escort model, the reactions of ATP binding and product release are coordinated with ssNA binding–unbinding by the subunits at the end of the staircase. In E1, the subunit at the top of the staircase (near the 5′ end of the NA) binds ATP and makes new interactions with an ssNA base, while the subunit near the 3′ end of the ssNA at the bottom of the staircase releases itself from the NA base. Thus, E1 moves in the 3′–5′ direction along the ssNA. The events in Rho are exactly the opposite as it moves with opposite polarity in the 5′–3′ direction. There, the subunit at the bottom of the staircase (3′ end of the RNA) makes new interactions with a NA base as it binds ATP and the subunit at the top releases a NA base as it releases Pi. The middle subunits are proposed to be in different states of prehydrolysis, hydrolysis, and post-hydrolysis states.

Based on the asymmetric binding of the ADP in E1 and ADP.BeF₃ in Rho at the six ATPase sites, the subunits are designated as ATP type, ADP type, or empty type. The subunits at one end of the staircase are ATP type (or prehydrolysis), the middle are ADP type (or hydrolysis competent), and at the other end of the staircase are open or empty type. The subunits that bind ATP tightly also appear to bind NA tightly, while the subunit that binds ATP weakly binds NA weakly as well.

The coordinated escort model is extremely appealing in terms of explaining how NTPase coordinated translocation of NA works to bring about processive movement. Future structures with ATP rather than ADP or ATP analogs will provide additional snapshots to define the proposed pathway. In addition, such intermediate structures will determine if all five subunits remain bound to ssNA through multiple cycles of ATPase.

Additional ways to verify the model are to measure the step sizes of the helicase. Both 2-site sequential model and 5-site coordinated escort model predict a mechanical step size (distance moved per ATPase) of 1 nucleotide. If a rate-limiting step occurs after each ATPase cycle, then a kinetic step size (number of bases translocated between two rate limiting steps) of one nucleotide should be observed. A kinetic step size of >1 nucleotide would indicate alternative mechanisms where multiple ATPase cycles lead to multiple base movement with intermediate rate-limiting step (similar to the stepping mechanism of Φ29 dsDNA-packaging motor, see below). Single molecule NA translocation studies are achieving high resolution to measure small steps and can distinguish between these possible mechanisms.

Translocation of dsDNA

Ring-shaped ATPases such as the packaging motors, FtsK, and RuvB bind and translocate on dsDNA without destabilizing the base pair (bp). Studies of the Φ29 dsDNA-packaging motor indicate a distinct mechanism of dsNA translocation.

The kinetics of dsDNA translocation by the $\Phi 29$ dsDNA-packaging motor were measured by single molecule optical tweezer experiments, which showed repetitive lag and burst phases of translocation. The lag phase depended on the ATP concentration and became shorter with increasing ATP, while the burst phase indicated translocation of 10 bp of dsDNA. These data appear to be inconsistent with the one ATP – one-step mechanism proposed for the ssNA translocases. Hence, a new latch-lever mechanism was proposed to explain the phenomenon, where multiple ATP molecules are loaded into the ring during the lag phase. Sequential ATP hydrolysis–product release then drives translocation of 10-bp dsDNA in steps of 2.5 bp with the hydrolysis of 1 ATP/2.5 bp. It was proposed that only a subset of the subunits binds dsDNA and translocation is brought about by global conformational changes in the ring. Many aspects of the above mechanism are yet to be tested by future ATPase kinetics and structural studies of the motor protein with NA bound to it.

Although studies of ssNA and dsNA translocases indicate more than one way of coordinating the ATPase and NA binding–unbinding cycles, it could be possible that there is a single underlying mechanism of NA translocation by ring ATPases that will gradually emerge as similar techniques of studying and interpreting the two kinds of motors happen. It is also possible that the packaging motors evolved differently from ssNA translocation motors to generate larger forces required to package the genomes in the capsids. Helicases such as T7 gp4, MCM, and DnaB can translocate on both ssDNA and dsDNA, and given the different structures of ssNA versus dsNA, it indicates that the central channel and the subunit coordination in the same helicase can be adjusted to accommodate both dsNA and ssNA translocation.

Mechanisms of NA Strand Separation

Replicative hexameric helicases typically show a high processivity in unwinding dsDNA. It is believed that helicases such

as T7 gp4, T4 gp41, *E. coli* DnaB, MCM unwinds dsDNA by translocating along ssDNA that they encircle while excluding the complementary strand of the dsDNA from the central channel at the fork junction (Figure 3). This mode of DNA binding (strand-exclusion model) minimizes immediate reannealing of the DNA strands after they are separated. Whether the excluded strand plays a steric role and simply excludes the helicase from encircling the dsDNA and translocating along it without strand separation or whether the excluded strand interacts with the outside region of the helicase ring to aid in strand separation is not established.

Many eukaryotic hexameric helicases like the viral SV40 large T antigen and bovine papilloma virus (BPV) E1, initiate unwinding by first binding to dsDNA of a specific sequence. These helicases destabilize the origin to initiate DNA replication with the help of other accessory proteins. However, it is not known if after melting the dsDNA at the origin, these helicases switch from dsDNA-binding mode to the strand-exclusion mode to catalyze replication fork movement. Models, such as ploughshare and ds melting mechanism, have been proposed as alternatives to the strand-exclusion model to explain DNA unwinding at the origin and translocation of the replication fork by helicases that do not require a fork to begin unwinding.

NA strand separation is typically measured *in vitro* using short dsDNA substrates either radiolabeled or fluorophore labeled. The strand-separation kinetics is monitored by polyacrylamide gel electrophoresis or by a stopped-flow fluorescence assay. Reannealing of the strands in the time-scale of the experiment is prevented by the use of low nM concentrations of DNA substrates in the assay and excess of the helicase protein. Recent advances in single-molecule studies have made it possible to study NA separation reaction by using fluorescence resonance energy transfers (FRETs) and magnetic or optical tweezers providing rates, sequence dependencies, pausing, and stepping behaviors of the helicase translocation.

The mechanism of NA strand separation has been investigated in some detail. NA strand separation involves breaking

Figure 3 Cartoon representing (a) active and (b) passive mechanisms of helicase unwinding. (a) In active mechanism of unwinding the helicase exerts a force (represented by the green cloud) at the fork-junction leading to breaking of the hydrogen bonds resulting in unwinding. (b) In passive mechanism of unwinding the helicase is an opportunist waiting to stabilize the broken base pair created by NA breathing, which happens at a faster rate at the forked junction and at a slower rate in the internal base pairs. In both cases, the helicase loads on one strand while excluding the complementary strand from its central channel.

the intermolecular forces mainly hydrogen bonds that hold the two strands together. Kinetic measurements show that T7 gp4, T4 gp41, DnaB translocate at a faster rate along ssDNA compared to their rates of dsDNA strand separation. Moreover, their dsDNA strand-separation rate depends on the GC content or the DNA stability. This raises the question as to whether helicases unwind the strands of the NA by a passive or an active mechanism (Figure 3).

In the passive mechanism, the helicase translocates on the ssNA as it is generated from thermal fraying of the dsNA. At physiological temperature, NA bp at the ss/ds junction open and close spontaneously, commonly referred to as 'breathing' of the NAs. The rates of spontaneous bp opening as measured by imino proton exchange, range from 30 s^{-1} for internal bp to 1000 s^{-1} for bp at the ss/ds junction. Although, individual bp opening is a fast process, the equilibrium for the reaction, $\text{ss} \rightleftharpoons \text{ds}$, lies toward bp formation and depends on the NA sequence and stability. A helicase-unwinding NA by a purely passive mechanism would be greatly affected by the NA sequence and stability as compared to a helicase-unwinding NA by an active mechanism. In the active mechanism, the helicase actively disrupts the bp at the junction to shift the $\text{ss} \rightleftharpoons \text{ds}$ equilibrium toward the left. Typically, the free energy of an AT bp is $1.3 k_B T$ and for the GC bp is $2.9 k_B T$. A passive helicase would have destabilization energy of $0 k_B T$ and an active one greater than that.

The destabilization energy for two ring-shaped helicases has been determined from rate measurements of DNA unwinding as a function of force or DNA sequence. By applying defined forces to the ss/ds junction using optical or magnetic tweezer, the junction bp can be destabilized to different extents. Similarly, by using DNAs with different GC content, the stability of the junction bp can be controlled. These experiments showed that T7 gp4 destabilizes the junction by $1\text{--}2 k_B T \text{ bp}^{-1}$, while $3.4 k_B T$ would be required to achieve the maximal translocation rate, indicating that T7 gp4 unwinds by a partially active mechanism.

Similar experiments showed that T4 gp41 destabilizes the bp by $0.05 k_B T$ and, thus, acts largely by a passive mechanism. It appears that force production by helicases can vary depending on their functions in the cell and by their association with accessory proteins. For example, replicative helicases work with motor proteins such as the DNA polymerase, which greatly increase helicase rates of strand separation.

Conclusions

A large number of helicases and helicase-like proteins have been identified by genome-sequencing efforts. With a basic understanding of the helicase activity, it is fairly clear that they have a quintessential role in DNA metabolism. Hence, any mutations in helicases can have serious consequences, and many are known to be associated with human diseases such as cancer and premature aging. Mutations in ERCC2 gene coding a helicase leads to *Xeroderma Pigmentosum*, Bloom's syndrome is caused by mutation in a gene coding for RecQ homolog, mutations in gene coding for TWINKLE cause adPEO, Werner's syndrome is caused by a gene coding a helicase and the list continues to grow.

Many viruses code for their own helicases, which make them unique targets for antiviral therapy. Understanding the structure and mechanisms of helicases is an important means of finding the link between the complex human diseases and helicases, which, in turn, would aid the drug-discovery process. From the viewpoint of understanding how helicases work, there is still a lack of a general mechanism that would explain NA strand separation and other functions performed by helicases at the molecular level. Despite all the differences in the properties and structures of helicases, it is possible that they function by similar mechanisms. It is likely that unidirectional translocation is a basic activity of all helicases responsible for NA strand separation and all other functions of helicases. This makes helicases similar to general motor proteins that translocate on lattices whose mechanism of operation may apply to helicases as well, and given a chance all motor proteins may be able to act as a helicase under the right conditions. New methodologies such as analysis of single helicase molecules *in vitro* and *in vivo* will allow direct observation of the helicase reaction, and more detailed information from these experiments will provide physical parameters that will reveal how helicases work. Even though helicases are a crucial factor for NA metabolism, it is worth noting that they need accessory proteins to carry out their functions efficiently. Hence, studying helicase activities in the context to its accessory partners will help to define their mechanism more precisely.

Glossary

Adenylation The reaction in which DNA ligase interacts with ATP or NAD to form a covalent enzyme–adenylate complex.

Motif An amino-acid sequence found to be conserved in different proteins.

Phosphodiester bond These bonds link together deoxynucleotides in DNA, forming the sugar phosphate backbone of the DNA polymer.

Phosphoramidite bond A covalent bond formed between a phosphoryl group and an amino group. For DNA ligases, the phosphoryl group of AMP is linked to the amino group of the active site lysine.

DNA ligases are a universal feature of DNA-based life forms and have almost ubiquitous involvement in DNA transactions. Using biochemical and immunological approaches, the laboratory of Tomas Lindahl provided the first evidence that mammalian cells contain more than one species of DNA ligase. This was confirmed by the cloning of three mammalian *LIG* genes. More recently, genome sequencing has revealed the presence of multiple *LIG* genes in the genome of some prokaryotes. Interestingly, some of these novel bacterial DNA ligases also possess primase, polymerase, and nuclease activities within the same polypeptide.

Reaction Mechanism

DNA ligase activity was first identified in 1967 in five different laboratories. In the years that followed, the Lehman laboratory was primarily responsible for elucidating the three-step reaction utilized by nicotinamide adenine dinucleotide (NAD)-dependent and adenosine triphosphate (ATP)-dependent DNA ligases that is described below.

Formation of Covalent Ligase–AMP Covalent Intermediate

In the first step, DNA ligase reacts with either NAD or ATP to form a covalent enzyme–adenosine monophosphate (AMP) intermediate (Figure 1). The AMP moiety is linked via a phosphoramidate bond to a conserved lysine that defines the active site of the catalytic core (Figure 2). During step 1, the catalytic region is in an extended, open conformation but the formation of the enzyme–AMP complex does result in relatively small conformational changes that are required for recognition of nicked DNA in the next step of the ligation reaction.

Formation of Covalent DNA–AMP Intermediate

The second step in the reaction involves the recognition of a DNA nick and the transfer of the AMP group to the 5' phosphate terminus of the nick in duplex DNA (Figure 1). Engagement of nicked DNA is accompanied by a major change in protein conformation. Specifically, the DNA ligase catalytic region encircles

the DNA nick, forming a compact, ring-shaped structure. Within the DNA–protein complex, the AMP moiety is positioned such that an oxygen atom in the phosphate group at the 5' phosphate terminus of the nick can attack the phosphoryl group of AMP, generating the 5' DNA–AMP intermediate.

Phosphodiester Bond Formation

The third and final step of ligation is catalyzed by nonadenylated DNA ligase that presumably retains the compact, ring-shaped conformation when it interacts with the DNA–AMP intermediate. In this reaction, nucleophilic attack by the hydroxyl group at the 3' terminus of the DNA nick results in esterification of the 5' phosphoryl group to the 3' hydroxyl group with the concomitant release of AMP (Figure 1).

Organization and Structure of DNA Ligase Catalytic Domain

Alignment of DNA ligase amino acid sequences indicates that these enzymes share a conserved minimal catalytic core that contains adenylation and oligonucleotide/oligosaccharide-binding (OB)-fold subdomains (Figure 2). Within this minimal catalytic core, there are six conserved amino-acid sequence motifs that are characteristic of the nucleotidyl transferase superfamily. In addition, all eukaryotic DNA ligases have a conserved DNA-binding domain (DBD) that is situated N-terminal to the catalytic core and is required for efficient ligation (Figure 2). The zinc finger (ZnF) and helix–hairpin–helix (HhH) motifs in the NAD-dependent *Escherichia coli* (*E. coli*) DNA ligase (Figure 2) appear to play an analogous role in DNA binding to the DBD of eukaryotic DNA ligases. A combination of mutagenesis, enzymology, and, in particular, structural biology has advanced our understanding of the mechanism of DNA joining by DNA ligases.

X-ray crystallographic studies of both NAD- and ATP-dependent DNA ligases have provided important insights into the three-dimensional structure of these enzymes and the dynamic conformational changes that are likely to occur as the enzyme interacts with the nucleotide cofactor and

Figure 1 Mechanism of phosphodiester bond formation by DNA ligase. Step 1: DNA ligase interacts with ATP or NAD forming a covalent enzyme-AMP intermediate. Step 2: after nick recognition, the AMP group is transferred to the 5' phosphate terminus forming a high-energy phosphate bond. Step 3: DNA ligase catalyzes phosphodiester bond formation, releasing AMP.

Figure 2 Features of the catalytic core and alignment of NAD- and ATP-dependent DNA ligases. (a) Schematic representation of the catalytic core shared by all DNA ligases that contains the six conserved motifs (I, III, IIIa, IV, V, and VI) characteristic of the NTases (nucleotidyl transferases); motif VI resides within the OB-fold domain that is separated from the adenylation domain by a linker. The active-site lysine is present within motif I, represented in red. (b) Comparison of a prokaryotic NAD-dependent DNA ligase (*Thermus filiformis*), and ATP-dependent DNA ligases from virus (bacteriophage T7), and humans (DNA ligases I, III α , and IV). DBD, DNA-binding domain; RFTS, replication factory-targeting sequence; ZnF, zinc finger motif; HhH, helix-hairpin-helix domain; BRCT, BRCA1 C-terminus domain; K, active lysine; OB, oligomer-binding; NLS, nuclear leader sequence; MLS, mitochondrial leader sequence; Ser, serine; aa, amino acid.

polynucleotide substrate. In 1996, the Wigley laboratory solved the first crystal structure of an ATP-dependent DNA ligase, the bacteriophage T7 DNA ligase, in a complex with ATP. This was followed by the structure of the enzyme–AMP intermediate formed by the *Chlorella* virus DNA ligase that was determined by the Shuman laboratory. A comparison of these structures revealed a conformational change in the DNA ligase catalytic core upon formation of the DNA ligase–AMP intermediate that allows binding to nicked DNA. Within the catalytic core, the larger adenylation subdomain is the minimum region required for formation of an enzyme–AMP intermediate whereas the OB-fold domain allows the enzyme to bind to DNA and coordinates the ligation event (Figure 2). Residues from motifs I through V line a cleft formed between the two subdomains to generate a positively charged nucleotide-binding pocket. The active-site lysine residue, which is contained within motif I, sits at the bottom of the cleft, close to where the adenylation domain and the OB-fold domain are linked. In the nonadenylated form, the enzyme is in an open conformation with the DNA-binding surface of the OB-fold domain rotated away from the active site thereby preventing nonproductive DNA binding. Upon adenylation, the enzyme undergoes a conformational change such that the DNA-binding surface of the OB-fold domain faces in toward the cleft, making the active site accessible.

The structure of a catalytically active fragment of human DNA ligase I determined by the Ellenberger laboratory was the first structure of a eukaryotic DNA ligase, but more importantly was the first structure of a DNA ligase complexed with nicked DNA. This revealed that the DNA ligase polypeptide encircles the DNA nick and distorts the DNA helix structure in the vicinity of the nick, exposing the nick termini. In this ring structure, the DBD, adenylation, and OB-fold domains each specifically interact with the nicked DNA. The DBD not only contacts the DNA upstream and downstream of the nick but also stabilizes the ring structure via protein–protein interaction with the adenylation and OB-fold domains. Subsequent studies have shown that the encircling of the DNA nick is a common feature of NAD-dependent DNA ligases and smaller ATP-dependent DNA ligases that lack the DBD domain.

DNA Ligase Polypeptides Encoded by the *LIG1*, *LIG3*, and *LIG4* Genes

The amino acid residues that flank the catalytic domain of ATP-dependent eukaryotic DNA ligases contain conserved domains

and/or motifs that mediate specific protein–protein interactions and protein–DNA interactions (Figure 2). These include the BRCT domain that was first identified in the breast cancer susceptibility gene 1 and is usually involved in protein–protein interactions, and the ZnF motif that is closely related to the two ZnFs that mediate DNA binding by poly (ADP-ribose) polymerase 1. The roles of the regions flanking the catalytic domain of ATP-dependent eukaryotic DNA ligases in defining the cellular activities of these enzymes are described below:

LIG1 (DNA Ligase I)

The unstructured N-terminal region of the DNA ligase I polypeptide is subjected to phosphorylation at several serine residues (Figure 2). These modifications occur during cell-cycle progression and regulate the participation of DNA ligase I in DNA replication and repair by modulating interactions with partner proteins. The N-terminal region of DNA ligase I also contains a nuclear localization signal (NLS) motif and a motif that acts as a replication factory targeting sequence (RFTS). Subsequently, it was shown that the RFTS corresponds to a proliferating cell nuclear antigen (PCNA)-binding motif (PIP box) and that the interaction with PCNA (Table 1) is critical for the participation of DNA ligase I in DNA replication and repair.

PCNA is a homotrimeric ring-shaped DNA-sliding clamp that was identified as a processivity factor for the replicative DNA polymerase, DNA Pol δ . Similarly, the interaction of DNA ligase I with PCNA rings, which are topologically linked to DNA, tethers DNA ligase I to the DNA. In addition, DNA ligase I also interacts with replication factor C (RFC), which loads the PCNA ring onto DNA and with the heterotrimeric DNA sliding clamp, Rad9–Rad1–Hus1, and clamp loader, hRad17–RFC, involved in cell-cycle checkpoints (Table 1).

LIG3 (DNA Ligase III)

Unlike DNA ligases I and IV, homologs of DNA ligase III are not present in lower eukaryotes, such as yeast, and may only be found in vertebrates. Notably, the *LIG3* gene encodes three distinct polypeptides (Figure 2). Nuclear and mitochondrial versions of DNA ligase III α are ubiquitously expressed from the same mRNA using different translation-initiation start sites. In addition, a germ-cell-specific form of DNA ligase III, DNA ligase III β , is generated by an alternative splicing mechanism in which the terminal 3'-coding exon in DNA ligase III α mRNA is replaced by a different exon, generating DNA ligase III β mRNA. The C-terminal 17–18 residues, which are unique

Table 1 Mammalian DNA ligases^a

Gene	Gene product	Interacting protein	Function
<i>LIG1</i>	DNA ligase I	PCNA, RFC, Pol β , Rad17–RFC, Rad9–Rad1–Hus1	DNA replication, BER, NER
<i>LIG3</i>	DNA ligase III α (nuclear)	XRCC1, NEIL1, TDP1, PARP1	SSBR, BER, NER, alt-NHEJ

to DNA ligase III β , function as a nuclear localization signal (Figure 2), whereas the 77 residues that are unique to DNA ligase III α contribute to a BRCT domain that specifically interacts with the DNA repair protein, XRCC1 (Figure 2). The interaction with XRCC1 is required for the stability and activity of nuclear DNA ligase III α .

All the DNA ligase III isoforms have an N-terminal ZnF domain that is closely related to the two ZnFs in the DBD of PARP1. Although the DNA ligase III ZnF is not required for ligation of DNA nicks, it acts in concert with the DNA ligase III DBD to bind to DNA single-strand breaks and is required for intermolecular ligation by DNA ligase III. The region between the ZnF and DBD contains a serine residue, Ser123, which is progressively phosphorylated by Cdk2 as cells progress through S phase and is dephosphorylated in response to DNA damage in a reaction dependent upon the ataxia-telangiectasia-mutated protein (ATM). As the region of DNA ligase III containing this serine mediates interaction with different proteins (Table 1), it is possible that the phosphorylation status of Ser123 regulates these interactions.

LIG4 (DNA ligase IV)

DNA ligase IV has an extended C-terminal region that contains tandemly arrayed BRCT motifs (Figure 2). The linker region between the two BRCT motifs mediates an interaction with the DNA repair protein XRCC4 that is required for the stability and activity of DNA ligase IV. DNA ligase IV stability is also influenced by phosphorylation of Ser650 by the DNA-dependent protein kinase (DNA-PK). Unlike DNA ligases I and III, the majority of DNA ligase IV molecules in the DNA ligase IV/XRCC4 complex, after purification, are pre-adenylated and only catalyze a single ligation event. However, the DNA repair protein XLF, which interacts with XRCC4, stimulates the joining of compatible and incompatible DNA ends by DNA ligase IV/XRCC4.

Cellular Functions of Eukaryotic DNA Ligases

As DNA joining is required to complete DNA replication, DNA repair, and genetic recombination, it appears likely that the multiple species of DNA ligase have evolved to participate in specific DNA transactions. Insights into the cellular functions of the different DNA ligases have been obtained by various approaches including phenotypic analysis of DNA ligase-deficient cells and the identification of interacting proteins (Table 1). The results of these studies are summarized below.

DNA Replication

There is compelling evidence that DNA ligase I is predominantly responsible for joining Okazaki fragments generated by discontinuous DNA synthesis on the lagging strand at the replication fork. For example, DNA ligase I-deficient cells exhibit a marked defect in Okazaki fragment joining, and DNA ligase I physically and functionally interacts with the replication proteins, PCNA and RFC. The surprising ability of mouse *lig1* null cells to proliferate suggests that another DNA ligase, most likely DNA ligase III α , is able to join Okazaki fragments in the absence of DNA ligase I.

Excision Repair

Damaged and mispaired nucleotides are removed from the genome by excision repair pathways that share three common steps: (1) excision of the damaged or mispaired DNA; (2) gap-filling DNA synthesis using the undamaged strand as template; and (3) DNA ligation to complete the repair. In base excision repair, the DNA damage is removed as a nitrogenous base by DNA glycosylase. Two subpathways of BER, long patch and short patch, have been defined based on the extent of repair synthesis. Short-patch BER events are mostly completed by DNA ligase III α in a complex with its partner protein XRCC1, whereas long-patch BER is completed by DNA ligase I. The hypersensitivity to DNA alkylating agents of both DNA ligase I- and DNA ligase III-deficient cells indicates that these subpathways are not functionally redundant. It is possible that the DNA ligase III-dependent short-patch pathway, which also involves DNA polymerase β , is a housekeeping pathway whereas repair by the DNA ligase I-dependent long-patch pathway, which involves other DNA replication proteins such as RFC and PCNA, is associated with DNA replication. Recent studies suggest that a similar situation occurs in the nucleotide excision repair pathway, in which DNA damage is excised as an oligonucleotide. Once again, DNA ligase III α appears to participate in a housekeeping subpathway in combination with DNA Pol δ , whereas DNA ligase I appears to participate in a replication-associated subpathway in combination with DNA Pol ϵ . The identity of the DNA ligase(s), which is involved in the mismatch repair pathway that removes mismatched nucleotides generated as a consequence of errors by the replicative DNA polymerases, has not been definitively established.

Repair of DNA Strand Breaks

DNA ligase III α is a key player in a repair pathway for DNA single-strand breaks, which appears to be restricted to higher eukaryotes. In this pathway, the single-strand breaks are recognized by PARP-1. This activates PARP-1 polymerase activity, resulting in poly-ADP-ribosylation of PARP-1 itself and other proteins. The DNA ligase III α /XRCC1 complex is recruited to the damage site by interaction with poly (ADP-ribosylated) PARP-1. XRCC1 acts as a scaffold protein, recruiting proteins that process the single-strand break to generate a ligatable structure.

In all organisms, efficient repair of double-strand breaks (DSBs) is critical for the maintenance of genomic stability and viability. These lesions are particularly difficult to repair because both strands of the DNA duplex are broken. The repair pathways for DSBs can be divided into two groups based on whether they are dependent upon extensive DNA sequence homology or not. The major homology-dependent DSB repair pathway in mammalian somatic cells utilizes the intact sister chromatid as the template to guide repair and so this repair pathway is restricted to stages of the cell cycle when sister chromatids are available, that is, late S and G2 phases of the cell cycle. The homology-dependent repair of DSBs during meiosis is also a critical component in the generation of haploid gametes. The identity of the DNA ligase(s) that is involved in homology-dependent repair of DSBs has not been definitively established. The germ-cell specific isoform of DNA ligase III, DNA ligase III β , may be involved in meiotic recombination.

In the pathways for the repair of DSBs that are not directed by DNA sequence homology, the DNA ends are simply brought together by DNA end-bridging factors, processed, and then ligated by DNA ligase IV. A consequence of this mechanism is that unlike the faithful sister chromatid-mediated repair of DSBs, the nonhomologous end joining (NHEJ) pathways are error prone, generating genetic changes ranging from small insertions and deletions at the break site to chromosomal rearrangements. Surprisingly, the majority of DSBs are repaired by NHEJ in mammalian cells. Repair of DSBs by the major NHEJ pathway is completed by DNA ligase IV/XRCC4 complex, which is recruited to the DSBs by interactions with DNA-PK. Similar to the repair of DNA single-strand breaks, end processing occurs. As DNA ligase IV/XRCC4, in conjunction with XLF, has the ability to join mismatched termini, the DNA ligation event itself may cause changes in DNA sequence. DNA ligase IV/XRCC4 and the core components of the major NHEJ pathway are also involved in the error-prone repair of site-specific DSBs that are generated during immunoglobulin gene rearrangements in immune-system cells. There is emerging evidence for an alternative NHEJ pathway that is more error prone than the major NHEJ pathway, in particular generating chromosomal translocations. Although the components and mechanisms of alternative NHEJ are not well defined, it does appear to involve DNA ligase III α /XRCC1.

Mitochondrial DNA Metabolism

The DNA replication and repair pathways described above are all active on the nuclear genome. Studies by the Campbell group have shown that a mitochondrial form of DNA ligase III α that is generated by translation initiation (**Figure 2**) plays a key role in mitochondrial DNA metabolism. In yeast, which lacks a *LIG3* homolog, a mitochondrial version of Cdc9 (DNA ligase I) is generated by the same mechanism. As XRCC1 has not been detected in mammalian mitochondria, the mitochondrial functions of DNA ligase III α are independent of XRCC1, and instead involve interactions with mitochondrial proteins such as DNA Pol γ (**Table 1**). The participation of DNA ligase III in both nuclear and mitochondrial DNA metabolism will complicate molecular genetic analysis of the cellular functions of DNA ligase III and may explain the absence of studies describing *lig3* null cells or mice.

Concluding Remarks

Although the mechanism by which DNA ligases catalyze phosphodiester bond formation was described over four decades ago, new insights into DNA ligase functions have been obtained recently from studies of DNA ligase-deficient cell lines, the identification of DNA ligase protein partners, the reconstitution of DNA repair pathways *in vitro* and atomic resolution structures of DNA ligases at different stages of the ligation reaction. This new knowledge not only deepens our understanding of the network of pathways that protect against cancer formation by maintaining genome stability, but also provides a framework for the development of novel clinical strategies that target DNA metabolic enzymes, such as DNA ligases, in highly proliferative cancer cells with abnormalities in the DNA damage response.

Glossary

Adenosine triphosphate (ATP) An adenosine-containing nucleotide that is used to provide energy for biochemical processes through hydrolysis of high-energy phosphate bonds.

Covalent nucleotidyl transferase A member of a family of enzymes that reacts with nucleotides and transfers the

nucleoside moiety to an acceptor molecule through the formation of a covalent nucleoside monophosphate (NMP)-enzyme intermediate.

Nicotinamide adenine dinucleotide (NAD⁺) A coenzyme present in all cells that accepts electrons to assist in metabolic processes; provides energy for biochemical processes through hydrolysis of high-energy bonds.

Introduction

The structural integrity of the genome is continually challenged by normal cellular activities that alter DNA structure, such as the processes of DNA replication, repair, and recombination. The stability of the genome is further challenged by exogenous sources of DNA damage, such as ultraviolet radiation and chemical carcinogens. DNA ligases make an essential contribution to maintaining genome integrity by correcting breaks, or nicks, in the phosphate backbone structure of duplex DNA. The vital importance of DNA ligases to the health of an organism is underscored by the fact that deficiencies in DNA ligase activity are associated with genetic instability and predisposition to cancer. The utility of joining fragments of DNA has also made DNA ligase enzymes a vital component of molecular biology techniques, such as gene cloning.

DNA ligases carry out a three-step reaction that results in the joining of two DNA strands: one with a 3'-hydroxyl terminus (3'-OH), and one with a 5'-phosphorylated terminus (5'-PO₄). The reaction mechanism requires a high-energy nucleotide cofactor, adenosine triphosphate (ATP) or nicotinamide adenine dinucleotide (NAD⁺), and DNA ligases are classified as being ATP-dependent or NAD⁺-dependent enzymes. The reaction mechanism also requires divalent cations such as Mg²⁺ or Mn²⁺. In step 1 of the reaction (Figure 1), the epsilon nitrogen atom of a conserved active site lysine side chain attacks the phosphorus atom of the adenosine monophosphate (AMP) group of ATP or NAD⁺, forming an N-P bond and creating the covalent ligase-AMP reaction intermediate. The nucleotide cofactor is hydrolyzed during the first step of the reaction, releasing pyrophosphate (PP_i) for ATP-dependent DNA ligases, or nicotinamide mononucleotide (NMN) for NAD⁺-dependent ligases. In step 2 of the reaction, the AMP group is transferred from DNA ligase to the 5'-PO₄ end of the DNA break, creating the covalent AMP-DNA reaction intermediate. In step 3 of the ligation reaction, the 3'-OH end of the DNA break is joined to the 5'-PO₄ end of the apposing DNA strand, liberating AMP and releasing the DNA substrate with a continuous phosphodiester backbone structure.

Domain Architecture of DNA Ligases

DNA ligases employ multidomain architectures to carry out the three-step ligation reaction mechanism. There are significant variations in the number and type of structural domains that compose the different DNA ligases (Figure 2). However, there are common structural domains found in all DNA ligases. The centerpiece of the DNA ligase structure is the nucleotidyltransferase (NTase) domain. The overall structural fold of the NTase domain is composed of α -helices surrounding a central arrangement of β -strands that form the nucleotide-binding pocket. The NTase domain houses six highly conserved amino acid sequence motifs that contribute key residues to the active site and form the nucleotide-binding pocket (Figure 2). Structures of DNA ligases in complex with nucleotide cofactors have demonstrated how the conserved sequence motifs position the cofactor and select for ATP or NAD over other nucleotides.

DNA ligases have an oligonucleotide/oligosaccharide-binding (OB) domain with a five-stranded β -barrel structure that extends from the C-terminus of the NTase domain (Figure 2). The OB domain is named for the OB properties of several domains that share this fold, although, in general, OB domains found in other types of proteins can also mediate other functions, such as protein-protein interactions. The basic NTase-OB domain structure is found in all DNA ligases. For the simplest DNA ligases, such as those from bacteriophage T7 and *Chlorella* virus, a two-domain NTase-OB architecture is sufficient to carry out all steps of DNA ligation. More complex DNA ligases decorate the basic NTase-OB domain structure with N- and C-terminal appendages that (1) assist the overall ligation reaction and/or (2) provide special DNA-binding properties that dictate substrate specificity, and/or (3) bestow special protein interaction properties that designate ligase activity to a particular cellular pathway of DNA repair. Several examples of these specialized domains are described in the following sections that detail how the multidomain structures carry out the three-step ligation reaction.

Figure 1 Three steps of the DNA ligation reaction and covalent intermediates. During step 1, the AMP (A_p) group of the nucleotide cofactor, ATP (A_{ppp}) or NAD^+ (A_pNMN), is attached to a conserved lysine of the ligase enzyme (E), forming the ligase-AMP intermediate (A_pE). During step 2, the AMP group is transferred to the DNA substrate containing a 5'- PO_4 ($pDNA$), forming the AMP-DNA intermediate ($A_{pp}DNA$). During step 3, the 3'-OH of an apposing nucleic acid strand (DNA_{OH}) attacks the 5'- PO_4 , joining the DNA ends and releasing AMP. The two covalent intermediates of the ligation reaction are drawn as sticks. The AMP-DNA intermediate is shown in the context of several nucleotides from the broken DNA strand; the complementary, intact DNA strand is not shown. The DNA break between the 3'-OH and the 5'- PO_4 is highlighted with an asterisk (*). Figure 2 Multidomain, modular architectures of DNA ligases. Representative domain architectures of ATP- and NAD^+ -dependent DNA ligases. The nucleotidyltransferase (NTase) domain is the centerpiece of all DNA ligases and houses the broadly conserved residues that catalyze the three-step end-joining reaction. The OB domain extends from the C-terminal end of the NTase domain and contributes key residues that assist in DNA ligation. A diverse collection of N- and C-terminal accessory domains extends from the NTase-OB domains to promote the ligation reaction, or to provide special substrate-binding properties: DNA-binding domain (DBD), helix-hairpin-helix (HhH) domain, domain Ia (Ia), zinc-binding domain (Zn), PARP-like zinc finger (ZnF), and BRCA-1 C-terminal (BRCT) domain. The two-domain crystal structure of bacteriophage T7 DNA ligase illustrates the fold of the NTase and OB domains found in all DNA ligases. ATP bound to the nucleotide-binding pocket of the NTase domain is drawn as sticks (blue). Adapted with permission from Pascal JM (2008) DNA and RNA ligases: Structural variations and shared mechanisms. *Current Opinion in Structural Biology* 18: 96–105.

Mechanisms of Ligase-AMP Formation

In step 1 of the ligase reaction, the covalent ligase-AMP intermediate is formed. ATP-dependent DNA ligases use conserved residues of the OB domain to assist in formation of the ligase-AMP intermediate (Figure 3). The OB domain of ATP-dependent ligases closes over the active site of the NTase domain to contribute residues that position the

α -phosphate of ATP for attack by the active site lysine. Interestingly, RNA-capping enzymes use a similar mechanism and a two-domain NTase-OB structure to form a covalent-capping enzyme-guanosine monophosphate (GMP) intermediate, prior to transferring GMP to the 5' end of messenger RNA. DNA ligases, RNA ligases, and RNA-capping enzymes constitute the covalent nucleotidyltransferase superfamily of enzymes.

Figure 3 Formation of the ligase–AMP intermediate. For ATP-dependent DNA ligases, the OB domain contributes key residues that stimulate the step 1 reaction, ligase–AMP formation. The open, extended conformation is modeled based on the *S. solfataricus* DNA ligase structure. The closed conformation, with the OB domain positioned next to the cofactor-binding site of the NTase domain, is based on the crystal structure of *P. furiosus* DNA ligase. Conserved residues that assist in step 1 are drawn as sticks (cyan). The transition of the OB domain from the open to closed conformation is highlighted by the arrow, and can be followed by noting the relative position of the helix of the OB domain marked with an asterisk (*), and the residues involve in step 1 chemistry (cyan). The domains are colored as in **Figure 2**: DBD (pink), NTase (green), and OB (yellow). For NAD⁺-dependent DNA ligases, domain Ia contributes key residues that stimulate the step 1 reaction. The open, extended conformation of domains is based on the structure of *T. filiformis* DNA ligase, which includes all ligase domains. The position of domain Ia during the step 1 reaction is based on the crystal structure of *Enterococcus faecalis* DNA ligase. Key residues from domain Ia that position NAD⁺ in the NTase active site for the step 1 reaction are drawn as sticks (cyan). The transition of domain Ia from the open to closed conformation is highlighted by the arrow and can be followed by noting the relative position of the helix of domain Ia marked with an asterisk (*), and the residues involve in step 1 chemistry (cyan). The domains are colored as in **Figure 2**: Ia (gray), NTase (green), OB (yellow), Zn (cyan), and HhH (pink).

In contrast to ATP-dependent DNA ligases, NAD⁺-dependent DNA ligases do not use their OB domain to assist in formation of the ligase–AMP intermediate. NAD⁺-dependent DNA ligases use a different mechanism that requires residues from an N-terminal extension of the NTase domain, called domain Ia (**Figure 3**). During ligase–AMP formation, domain Ia closes over the active site of the NTase domain to bind the NMN moiety of NAD⁺ and position the nucleotide cofactor for attack by the active site lysine. Thus, both NAD⁺- and ATP-dependent DNA ligases use accessory domains to promote ligase–AMP formation, but they do so using entirely different domains and mechanisms. After formation of the ligase–AMP reaction intermediate, domain Ia and the OB domain pivot away from their respective NTase active sites to allow access to incoming DNA substrates; therefore, large-scale conformational changes accompany the binding and hydrolysis of NAD⁺ or ATP.

Mechanism of AMP–DNA Formation and DNA End Joining

Crystal structures of several DNA ligases bound to nucleic acid have provided instructive views of ligase enzymes engaging their DNA substrates and nucleotide cofactors at different stages of the ligation reaction. The structures illustrate how breaks in DNA are recognized, how AMP is used to orchestrate ligation chemistry, how novel accessory domains are utilized

in catalysis and substrate recognition, and how the shape of the DNA substrate plays an important role in the ligation reaction. The DNA ligase structures in complex with DNA indicate that large-scale changes in domain arrangements accompany nucleic acid binding. Furthermore, the structures have revealed that DNA ligases form protein clamps that encircle their DNA substrates; however, the ligase clamps are formed using distinct topological arrangements of their domains (see the following section).

DNA ligases were trapped in complex with DNA for crystallographic analysis by stalling DNA ligation at different steps along the reaction pathway. The catalytic fragment of human LIG1 was crystallized in complex with the AMP–DNA reaction intermediate. A 2'-H, 3'-H dideoxy nucleotide at the 3' end of the DNA break stalled the ligation reaction after AMP–DNA formation – the absent 3'-OH prevented the final DNA end-joining reaction from occurring. The structure of *Escherichia coli* DNA ligase A (LigA) was also determined in complex with the AMP–DNA reaction intermediate. A 2'-H, 3'-OH deoxynucleotide at the 3' end of the DNA break made the substrate competent for ligation; however, divalent metals were excluded from crystal solutions to prevent ligation of DNA ends. The ligase–AMP intermediate of *Chlorella* ligase was crystallized bound to a DNA break with 3'-OH and 5'-PO₄ ends, showing the arrangement of a ligase active site before AMP is transferred to DNA. Divalent metals were excluded from crystal solutions, and this stalled the ligation reaction prior to step 2. After the addition of divalent metal to the *Chlorella* ligase

crystals, the broken DNA ends were joined together, highlighting that the *Chlorella* ligase–DNA complex is truly paused along the ligation reaction pathway. The ligase–AMP intermediate of human DNA ligase III (LIG3) was also crystallized in complex with DNA; the DNA break was not competent for ligation due to a 2'-H, 3'-H dideoxy nucleotide at the 3' end of the DNA break.

Collectively, the DNA ligase structures in complex with DNA demonstrate that the NTase and OB domains interact to form a continuous protein surface that engages the DNA minor groove at the break in the DNA substrate (Figures 4(a) and 4(b)). The NTase–OB interaction with DNA creates a localized change in substrate conformation at the DNA break, imposing an RNA-like A-form configuration on the substrate, resulting in a widened and more shallow minor groove compared to B-form DNA (Figures 4(c) and 4(d)). The distortion of the substrate partially unwinds the DNA duplex and alters the trajectory of the helical axis at the break in the DNA. The local alteration of the substrate conformation extrudes the DNA ends from the DNA duplex and positions them in the active site for the joining reaction. Each of the DNA ligase structures in complex with DNA demonstrate a similar arrangement of their NTase and OB domains on the DNA break, although there are variations in the amino acid residues and structural elements that mediate the interactions. However, in each of the DNA ligase structures bound to DNA, the NTase

and OB domain interactions with the minor groove conspire to impose an RNA-like A-form conformation on the substrate at the DNA break.

The NTase domain primarily interacts with the substrate on the 3' side of the DNA break, making contacts to the phosphodiester backbone of the broken and intact DNA strands, and placing conserved amino acid residues in the minor groove near the DNA break. These residues position the 3'-OH end of the substrate within the active site for the ligation reaction to occur. The NTase domain positions the 5' side of the break primarily through contacts with the AMP group, which is covalently linked to the 5'-PO₄ of DNA. The OB domain primarily engages the 5' side of the break, spanning the minor groove and making extensive contacts with the phosphodiester backbone of both the intact strand and the broken DNA strand. In collaboration with the NTase domain, the OB domain contributes residues to the minor groove around the DNA break to assist in creating the local A-form distortion that positions the DNA ends in the active site. The ligase–AMP intermediates of *Chlorella* DNA ligase and human LIG3 were crystallized in complex with a DNA break containing the required 5'-PO₄ end. In these structures, the NTase and OB domains engage the DNA substrate in the same manner shown for LIG1 and LigA (Figures 4(a) and 4(b)), indicating that the NTase–OB configuration is consistent during the step 2 and step 3 reactions. Notably, the DNA-bound

Figure 4 The NTase and OB domains engage the minor groove at the DNA break. A detailed view of NTase–OB interactions with the DNA minor groove for (a) human Ligase I and (b) *E. coli* Lig A. The NTase domain (green) and OB domain (yellow) are drawn as tubes. The AMP cofactor (blue), the broken DNA strand (light gray), the intact DNA strand (dark gray), residues involved in minor groove interactions (red), and the active site lysine (red) are drawn as sticks. The break in the DNA substrate is highlighted with an asterisk (*). The 3' and 5' sides of the DNA break are labeled for LIG1 in (a), and (b) has the same orientation. (c) DNA ligase binding to the minor groove distorts the DNA substrate near the break in the phosphodiester backbone. The minor groove is made wider and less deep, with dimensions more similar to A-form duplex. The substrate distortion positions the DNA ends toward the ligase active site (red arrow). The overall shape and dimensions for ideal B-form duplex DNA is shown in (d) for comparison. Adapted with permission from Pascal JM (2008) DNA and RNA ligases: Structural variations and shared mechanisms. *Current Opinion in Structural Biology* 18: 96–105.

orientation of the OB domain is dramatically different from the orientation of the OB domain during step 1. The transition between the two active conformations of the OB domain requires a 180° swiveling of the OB domain around its linker to the NTase domain.

DNA Ligase Protein Clamps

A remarkable feature of the DNA ligase structures in complex with DNA is that the enzymes form protein clamps that fully encircle the substrate DNA (Figure 5). Even more remarkable is that the protein clamps are formed using different strategies for different DNA ligases, as further described below. There are two key reasons why this might be important for DNA ligase function. First, engulfing the DNA ends within the ligase domain structure fully protects the DNA break from exposure to other cellular factors that might act on the DNA

ends, such as nucleases. Second, the protein clamp allows a more extensive interaction surface with the DNA substrate. This could be important for DNA ligases to properly engage DNA substrates, which are quite large relative to the size of the ligase enzyme.

As mentioned previously, ATP-dependent eukaryotic and archaeal DNA ligases have multidomain architectures. In addition to the NTase–OB catalytic core, they have an N-terminal α -helical extension termed the DNA-binding domain (DBD; Figures 5(a) and 5(b)). The DBD of human LIG1 and LIG3 stimulates the ligation activity of the NTase and OB domains, indicating that the DBD acts cooperatively with the NTase–OB catalytic core by supporting their active conformation on DNA and the distorted shape of the substrate DNA. As shown for human LIG1, the DBD binds across the minor groove of the DNA substrate at two positions, equally spaced around the break in the DNA (Figure 5(b)). The α -helical fold of the DBD has pseudo-twofold symmetry, providing similar

Figure 5 DNA ligase protein clamps. Surface representations of DNA ligase protein clamps: (a) Human LIG1, (c) *E. coli* LigA, and (e) *Chlorella* ligase. Double-headed arrows indicate breakpoints in the ligase clamps. Domains are labeled, and colored as in Figure 2. For clarity, DNA substrates are not shown in (a), (c), and (e). Cartoon representations of DNA substrates bound to (b) the DBD of human LIG1, (d) the HhH of *E. coli* LigA, and (f) the latch of *Chlorella* ligase. The helical axis of the DNA substrate is shown for LIG1 in (a), highlighting the local distortion that occurs at the DNA break. The orientations of (b), (d), and (e) are rotated roughly 90° relative to the orientations in (a), (c), and (e), respectively. protein–DNA interaction motifs on both sides of the DNA break. The DBD physically interacts with the NTase and OB domains, establishing a ligase protein clamp that fully encircles the DNA substrate. The DBD is required for the ligation activity of several eukaryotic ligases, and the DBD residues that mediate interactions with DNA substrate are conserved among other human DNA ligases. It is, therefore, expected that all eukaryotic ligases encircle DNA when carrying out the end-joining reactions required for the replication and repair of DNA.

The eukaryotic DBD may have additional functional roles. DNA ligases from *Pyrococcus furiosus* and *Sulfolobus solfataricus* interact with the proliferating cell nuclear antigen (PCNA) DNA sliding clamps of these organisms using residues located in their respective DBDs. For these archaeal DNA ligases, the DBD interaction with PCNA stimulates ligation activity. The DBD interaction with PCNA is conserved in humans, where the DBD of LIG1 interacts with human PCNA. The function of this interaction has not been established, but it may play a role in coordinating LIG1 activity during replication and repair.

Mammalian ligases (LIG1, LIG3, and LIG4) have extra domains that extend from the N- and C-termini of their shared catalytic DBD–NTase–OB architecture, and these appended domains provide unique DNA-binding or protein–protein interaction properties that endow specificity for different DNA replication and repair pathways. Understanding the

structure and function of these distinguishing features of mammalian ligases will play an important role in determining their mechanistic roles in cellular DNA metabolism.

Bacterial DNA ligases are almost exclusively NAD^+ -dependent enzymes. They have multidomain architectures that are quite different from the eukaryotic ATP-dependent DNA ligases, although the NTase and OB domains still form the core of these enzymes. In addition to the unique N-terminal domain Ia that stimulates ligase–AMP formation, there are three C-terminal domains that extend from the OB domain: a small zinc-binding (Zn) domain, a helix–hairpin–helix (HhH) domain, and a BRCT domain (BRCA1 gene C-terminus). Biochemical analysis of *Thermus filiformis* ligase indicates that the BRCT domain is not important for the ligation reaction *in vitro*, and the *in vivo* function of the BRCT domain is not clear.

The structure of *E. coli* LigA in complex with DNA demonstrates the arrangement of bacterial ligase domains when engaging substrate nucleic acid, revealing a novel ligase protein clamp that encircles the DNA substrate (Figure 5(c)). On the side of the DNA substrate opposite to the NTase–OB domains, the HhH of LigA binds to DNA with approximate twofold symmetry, gripping the DNA across the minor groove at two positions spaced symmetrically about the break (Figure 5(d)). The HhH domain of LigA extends from the OB and Zn domains and contacts the NTase domain, creating a protein clamp that envelops the DNA substrate. The DNA-bound

Step 1, ligase–AMP formation

Steps 2 and 3, AMP–DNA formation and ligation

Figure 6 Conformational rearrangements during the DNA ligation reaction. A schematic model for DNA ligase conformational changes during the DNA end-joining reaction based on crystal structures of ATP-dependent DNA ligases. (Top) To form the ligase–AMP reaction intermediate during step 1, the OB domain (yellow) moves toward the NTase domain (green) to place conserved residues (brown half-oval) near the ATP-binding site. Inorganic phosphate (PP_i) is released after nucleotide hydrolysis, and ligase returns to the open conformation in order to provide access to substrate DNA. (Bottom) Upon binding to nicked DNA, the OB domain pivots and moves toward the NTase domain and the bound DNA substrate. This conformation of the OB domain places conserved residues (blue trapezoid) near the break in the DNA and contributes to AMP–DNA formation and ligation of DNA ends. AMP and DNA with a continuous backbone structure are released. The configuration of domains in the middle of the top and bottom panels represents the two active conformations of DNA ligase. The transition between the two active conformations of the OB domain requires a 180° swiveling of the OB domain around its linker to the NTase domain. The DBD domain (red) contributes to DNA-binding affinity, and supports the arrangement of the NTase–OB domains and the distorted DNA substrate conformation.

conformation of the LigA domains is remarkably different from the arrangement of domains observed in the ligase–AMP intermediate of *T. filiformis* ligase in the absence of DNA, demonstrating that large-scale alterations in domain arrangements occur upon binding to DNA breaks. The Zn domain bridges between the OB and HhH domains of LigA, most likely providing structural support for the modular ligase architecture as it reorganizes during the steps of DNA ligation.

The HhH domain of LigA and the DBD of LIG1 appear to play analogous functional roles, despite having entirely different protein folds. They both occupy similar positions on the DNA substrate in their respective protein clamps, and they both engage DNA in similar manners, primarily using polar atoms of the protein main chain to brace the phosphodiester DNA backbone. Similarly, both the DBD of LIG1 and the HhH domain of *T. filiformis* provide the major DNA-binding activity for these ligases. The distinct topology and connectivity of the LIG1 and LigA domain architectures indicate that the eukaryotic and bacterial protein clamps are independent yet strikingly similar solutions to encircling DNA breaks.

Chlorella virus PBCV-1 encodes a 298-residue DNA ligase with a two-domain NTase–OB architecture that lacks the flanking accessory domains required by the cellular eukaryotic and bacterial ligases. *Chlorella* ligase displays yet another distinct protein clamp that encircles the DNA substrate (Figure 5(e)). The OB domain of *Chlorella* ligase has a 30-residue surface loop, designated the ‘latch’, that forms extensive contacts with the phosphodiester backbone of the major groove opposite the break in the DNA (Figure 5(f)). The distal end of the latch contacts the NTase domain to complete a protein clamp that encloses the substrate DNA. The latch was disordered in an unliganded crystal structure of *Chlorella* ligase, and protease sensitive in solution in the absence of DNA, indicating that the latch only becomes ordered upon binding to DNA. The latch is substantially smaller than the DBD and HhH domains, yet it appears to play a similar role in providing the major contribution to DNA binding.

The collection of DNA ligase structures bound to nucleotide cofactors and to DNA substrates have illustrated how the multidomain architectures of DNA ligases carry out the three-step ligation reaction. A stunning level of conformational plasticity is required to perform the steps of DNA ligation, as illustrated in the cartoon depiction of the ligase reaction based on several structures of ATP-dependent eukaryotic DNA ligases (Figure 6). The variety of DNA ligase domain architectures has converged on a common principle of encircling DNA substrates to assist in manipulating the broken ends of DNA for the joining reaction. The structures have also detailed the dramatic mechanistic differences between the bacterial NAD⁺-dependent and

eukaryotic ATP-dependent ligases during the step 1 reaction, as well as key mechanistic differences between the eukaryotic and the viral ATP-dependent DNA ligases. Due to the fundamental requirement for DNA ligase activity in all organisms, and the important role of ligases in maintaining genome integrity, selective inhibitors of ligase activity are potential antimicrobial agents and novel tools for fighting cancer. The specific molecular level insights into the ligation mechanism derived from structural analysis provide new avenues for the design of selective inhibitors of DNA ligase activity.

Glossary

DNA methyltransferase Enzyme that transfers a methyl group to a base in DNA.

Epigenetic Pertaining to phenotypic, but not genotypic, change.

Exonuclease Enzyme that digests DNA strand from an end.

Hemimethylated Describing DNA in which one strand contains methylated residues but the complementary strand does not.

Promoter Sequence at which RNA polymerase initiates transcription.

Properties of Dam Methyltransferase

The Dam methyltransferase is encoded by the DNA adenine methyltransferase (*dam*) gene of *Escherichia coli*, which has a complex mechanism of gene regulation involving multiple promoters and terminators. The major promoter for transcription of the gene is regulated by growth rate of the cells; that is, the faster the growth rate, the greater is the level of initiation of transcription.

During chromosome replication, the replication fork is followed by a region of hemimethylated DNA which comprises new unmethylated DNA and the complementary methylated template strand. After 1 min, on average, in slow-growing cells the newly synthesized DNA is methylated so that both strands are fully methylated. This delay in methylation is due to the concentration of the Dam methyltransferase; it is present at 130 molecules per cell. Increasing the cellular concentration of the enzyme proportionately decreases the amount of hemimethylated DNA.

The enzyme is a single polypeptide chain of 278 amino acids with a molecular weight of 32 kDa and exists in solution as a monomer. The enzyme has a turnover number of 19 methyl transfers per minute and an apparent K_m of 3.6 nM for DNA; double-stranded DNA is a better methyl acceptor than denatured DNA; and there is one methyl transfer per site per binding event even if the substrate DNA is fully unmethylated. In contrast to these findings, there is also evidence that the Dam methyltransferase binds the template and slides processively along the DNA, methylating about 50 sites before dissociating. The differences in distributive and processive activity may be dependent on the length, sequence, and topology of DNA. The atomic structure of Dam complexed with DNA has been solved and shows both nonspecific backbone contacts and specific contacts with the glutamyl-tRNA (Gln) amidotransferase, subunit C homolog (GATC) bases. Importantly, the aromatic ring of Y119 intercalates into the DNA between GA and TC, thereby flipping the adenine into the enzyme's active site. The unpaired complementary T residue can adopt an intrahelical or extrahelical position. The contacts of the enzyme with GATC bases, and flanking phosphate contacts by conserved residues, position Dam on the DNA duplex.

Properties and Uses of *dam* Mutant Strains

The commonly used *dam* mutant strains have neither detectable residual methyltransferase activity nor detectable methylation at GATC sequences. *Dam* mutants are most often used to launder DNA molecules that have sites that are resistant to digestion with specific restriction endonucleases. These include AlwI, BcgI, BclI, BsaBI, BspDI, BspEI, BspHI, ClaI, HphI, NruI, TaqI, and XbaI. Resistance occurs because these enzymes have recognition sequences that overlap with the GATC tetranucleotide and almost all of these are methylated in wild-type *E. coli*. After transfer through the *dam* mutant strain, there is no methylation at GATCs and DNA molecules are now sensitive to digestion with the restriction endonucleases listed above.

Dam mutants have also been useful to define the biological roles of methyl groups on adenine in DNA. The mutant strain shows a large number of phenotypic differences compared to wild type suggesting multiple functions. All the known mutant phenotypes in *E. coli* can be explained by the involvement of GATC methylation in mismatch repair, regulation of gene expression, and initiation of chromosome replication.

Dam-Directed Mismatch Repair

During chromosome replication, errors are made at low frequency by the replicative polymerase to form base mismatches in newly synthesized DNA. Such errors need to be removed because they are potentially mutagenic. *E. coli* and most other organisms, including humans, have a highly conserved repair system that removes such mismatches in newly synthesized DNA. The Dam- (or methyl-)directed mismatch repair system in *E. coli* uses only hemimethylated DNA as a substrate, thereby restricting its activity to the region of the chromosome immediately trailing the replication fork. The repair system is outlined in [Figure 1](#). Briefly, base mismatches in hemimethylated DNA are recognized by the MutS protein followed by the formation of a ternary complex with two additional proteins, MutL and MutH. MutH is an endonuclease active on hemimethylated GATC sites but only when complexed with the other Mut proteins on DNA. Following DNA incision, the UvrD helicase unwinds DNA in

Figure 1 DNA mismatch repair. A base mismatch (M) in the newly synthesized unmethylated DNA strand is some distance from the nearest GATC sequence. MutS protein binds the mismatch and a complex with MutL and MutH is formed leading to cleavage of the unmethylated strand. The UvrD helicase unwinds the unmethylated strand which is digested by an exonuclease. Excision can occur in either the 3'–5' direction (ExoI and ExoX) or the reverse (RecJ and ExoVII), depending on the orientation of the mismatch relative to the GATC sequence. DNA polymerase III holoenzyme synthesizes a new strand and the resultant nick is ligated by DNA ligase. The GATC sequence is eventually methylated by Dam methyltransferase.

either the 5'–3' direction or the reverse. The directionality is dependent on the location of the mismatch relative to the nearest GATC sequence. The unwound nicked DNA strand is digested by one or more exonucleases, followed by resynthesis using the replicative polymerase. DNA ligation of the nick at the end of replication completes the process of repair and the hemimethylated DNA is eventually methylated.

Three lines of genetic evidence indicate the importance of DNA methylation in the process. First, overproduction of Dam methyltransferase inhibits the repair process by reducing the amount of hemimethylated DNA. Under these conditions, mismatches are not repaired and lead to an increase in mutation frequency. Second, in a *dam* mutant the repair system is active but cannot discriminate the template strand from the daughter strand. Consequently, the repair system not only removes mutations from the newly synthesized strand but also introduces mutations into the parental strand, yielding an increased mutation frequency. Third, DNA duplexes containing a mismatch can be constructed with no methylation, methylation on both strands, or on only one of the two strands. When introduced into cells the fully methylated DNA is not repaired, hemimethylated DNA is repaired using

the methylated strand as template, and the unmethylated duplex is repaired using either strand as template.

In a *dam* mutant, mismatch repair produces detectable nicks or gaps in DNA but it is not known if the nicks or gaps occur exclusively behind the replication fork as a result of replication errors or in any part of the chromosome as a result of mismatches formed spontaneously. The nicks or gaps are converted to double-strand breaks either by a replication fork encountering an unrepaired gap or by an activated MutH cleavage on complementary strands at the same GATC sequence or by a combination of these (Figure 2). It is not yet known which of these mechanisms (or both) generates double-strand breaks *in vivo*; however, *in vitro* evidence supports the MutH cleavage model.

Mismatch repair in *dam* mutants is also the basis for the phenomenon of drug tolerance. The mutants are more sensitive than wild type to certain anticancer agents, such as cisplatin, and certain methylating agents. Inactivation of mismatch repair, however, renders the cell tolerant to these agents. In other words, mismatch repair sensitizes *dam* cells to the effects of these deleterious agents. This is of interest because mammalian cells in culture respond in exactly the same way;

Figure 2 Generation of double-strand DNA breaks. (a) Mismatch repair endonuclease MutH introduces nicks on either side of a GATC sequence to produce a double-strand break. (b) Mismatch repair introduces a nick ahead of a replication fork producing a double-strand break when the fork encounters it. Recombination is required to restore the fork.

that is, they are sensitive to these agents but become tolerant upon loss of mismatch repair capacity. In *dam* cells exposed to a methylating agent, there is an increase in the level of DNA double-strand breaks but these are not present in *dam* cells deficient for mismatch repair. In other words, it is the action of mismatch repair that produces double-strand breaks. DNA double-strand breaks are repaired by homologous recombination but there is *in vitro* evidence that the MutS and MutL proteins inhibit the initial stage of recombination if the substrate DNA has been exposed to a methylating agent. The loss of viability in *dam* bacteria exposed to a methylating agent may, therefore, be due to both the formation of double-strand breaks and the suppression of their repair by mismatch repair enzymes. In mammalian cells exposed to a methylating agent, the molecular basis for mismatch-repair-dependent killing has yet to be defined.

Initiation of Chromosome Replication

In *E. coli*, chromosome replication is initiated only once per cell cycle and Dam methylation is involved in this process. Chromosome replication is initiated at *oriC*, a region which has a 10 times higher than expected density of GATC sequences, by the initiation protein DnaA. The promoter region of the *dnaA* gene

must be methylated for maximal expression and methylated origins are more efficiently initiated than unmethylated ones. Initiation of chromosome replication produces hemimethylated DNA but the region surrounding *oriC* remains hemimethylated for a period of time equal to about one-third of the cell cycle. During this eclipse period, the hemimethylated *oriC* and *dnaA* gene region is bound specifically and with high affinity by the SeqA protein, which prevents methylation by Dam methyltransferase and renders the origin inert to further initiation. By a process that is not understood, SeqA is released from *oriC* later in the cell cycle and methylation ensues, followed subsequently by another initiation event.

The eclipse period is dependent on the level of Dam methyltransferase and can be lengthened or shortened by decreasing or increasing the enzyme level, respectively. *In vivo*, *dam* and *seqA* mutants have an asynchronous initiation pattern and the eclipse period is shortened or absent. The *seqA* mutant, as expected, performs extra initiations at each cell cycle but the *dam* mutant does not. This indicates that in *dam* mutants there must be an alternative mechanism preventing excessive initiation.

In fast-growing cells, the time required to replicate the bacterial chromosome exceeds the culture doubling time, and initiation of replication may take place one, two, or even three generations prior to cell birth. Consequently, cells are born with replicating chromosomes and contain multiple origins of replication. Initiation of replication in such cells takes place only once at each origin within a short time interval of the cell cycle, leading to synchronous initiation. Dam methylation, despite facilitating duplex opening at *oriC*, is not essential for replication. Rather, methylation of these sites is instrumental in maintaining initiation synchrony, because it allows for discrimination between an old uninitiated origin and one that has recently been initiated.

Altered Gene Expression

In wild-type *E. coli*, GATC sequences can be methylated on both strands, hemimethylated or unmethylated. These configurations are used by specific proteins to bind to DNA. For example, as discussed, the *dnaA* gene is maximally transcribed only if the promoter region is fully methylated. This is consistent with its role in the initiation of chromosome replication. Presumably, since *dnaA* gene expression is autoregulated and that DnaA can act as an activator/repressor, fully methylated GATCs act to modulate DnaA binding. The mismatch repair protein, MutH, and the nucleoid organizing protein, SeqA, bind specifically to hemimethylated sequences. There is also evidence that unmethylated GATC sites are protected from Dam by specific binding of regulatory proteins (Fnr and Cap, see below).

The promoter for the *tsp* (transposase) gene of the mobile genetic element, *Tn10*, is active only when it is hemimethylated, thereby ensuring that transposition is coupled with chromosome duplication and occurs only once per cell cycle. A further example is the pyelonephritis-associated pilus (*pap*) operon in pathogenic *E. coli*, where a Pap protein and the transcriptional activator Lrp compete for binding to two specific symmetrically

unmethylated GATC sequences. Depending on which protein is bound to which GATC, *pap* expression is either off or on.

There are few other genes where the rationale of coupling methylation to gene expression is so clear-cut. High-density oligonucleotide array analysis of messenger RNA (mRNA) from *dam* mutants indicates that expression of many genes is altered. In several instances, this is due to competition between Dam methyltransferase and transcriptional activators such as Fnr and Cap competing for the GATC sites that overlap their recognition sequences. For other genes such as *sula* (involved in control of cell division) and *glnS* (glutamyl-tRNA synthetase), which have GATCs in their promoter regions, expression is increased when they are unmethylated. The biological rationale for this is not known. There are also many examples where GATCs in the promoter region have no effect on initiation of transcription. At present, there are no rules to predict if a GATC sequence in the promoter will increase, decrease, or have no effect on the frequency of transcription initiation.

As discussed, *dam* mutant DNA is subjected to DNA breakage *in vivo*. This results in the induction of a stress response termed International Distress Signal (SOS) in which transcription of about 50 genes is increased. The gene products include those that repair DNA damage, recombination, and control cell division. In *dam* mutants, this response is constitutively expressed because three recombination proteins (RecA, RuvA, and RuvB), which are part of the response, are required for cell viability.

Role of Dam Methylation in Bacterial Pathogenesis

Altered levels of Dam methyltransferase can modulate the virulence of certain bacterial pathogens, including *Actinobacillus*, *Aeromonas*, *Brucella*, *Campylobacter*, *Haemophilus*, *Klebsiella*, *Pasteurella*, *Salmonella*, *Vibrio*, and *Yersinia* in animal models and in *Erwinia*, a plant pathogen. The best-studied system is the *Salmonella* mouse model. *Dam* mutant *Salmonella* are 10000 times less capable of killing mice than wild type but a low level of tissue infectivity occurs. Mice that have been infected with the avirulent *dam* mutant become much more resistant to killing by wild-type *Salmonella*, suggestive of a vaccine effect. The molecular basis for the role of Dam methylation in bacterial pathogenesis has yet to be elucidated but the following virulence-related defects have been described for *dam* cells: reduced interaction with intestinal epithelium, reduced motility, envelope instability, increased Std fimbriae, and bile salt sensitivity. It is probable that not all bacterial pathogens will fit with the *Salmonella* mouse model.

Cell functions under control of Dam methylation in various pathogens include secretion of virulence effectors, toxin synthesis and export, flagella and motility, and fimbrial and nonfimbrial adhesins. It is probable that for many of these virulence factors an alteration in Dam-dependent transcription initiation is responsible.

A contrast to the *Salmonella* example is provided by *Neisseria* that can cause meningitis. These bacteria have a *dam* gene but it is not involved in pathogenesis. Rather, it is the defects in the mismatch repair system (*mutS* and *mutL* gene inactivation) that allows for frameshift mutations to occur in DNA sequences controlling expression of certain virulence genes. There is no

general rule about the effect of Dam methylation on virulence; it has to be investigated for each organism.

Posttranscriptional Regulation by Dam Methylation

As discussed, there are many examples of Dam-dependent alteration of transcription initiation of particular genes. There are also a few instances of posttranscriptional regulation affected by Dam methylation. The *dcm* gene is on the same mRNA transcript as the *vsr* gene, which is a component of the very-short-patch (VSP) repair pathway. The level of Dcm in wild-type cells is the same in logarithmic or stationary phases of growth but Vsr is produced only in stationary phase. In a *dam* mutant, there is no production of Vsr at any stage of the growth curve.

Enterohemorrhagic *E. coli* produce, and sit on, raised projections (pedestals) on the surface of mammalian cells grown in culture medium. Pedestal formation requires bacterial secreted proteins including Tir and intimin, which are encoded on the same mRNA transcript. *Dam* mutants produce a greater frequency of pedestals and contain increased levels of Tir and intimin but there is no change in the steady-state level of the mRNA encoding them. *Dam* overproduction in *Yersinia enterocolitica* causes numerous metabolic alterations, including a change in the composition of lipopolysaccharide O-antigen. However, there is no change in the mRNA levels for the genes responsible compared to wild type. The genes of pathogenicity island, SP-1, of *Salmonella enterica* are affected by Dam methylation at both the transcriptional and posttranscriptional levels. A model to explain these Dam-dependent posttranscriptional effects invokes the altered transcription of intergenic small regulatory RNA molecules which in turn regulate translation of the affected genes.

Role of Dam Methylation in Other Bacteria and Their Viruses

At present, little is known about the role of Dam methylation in other bacteria. Inactivation of the *dam* gene in *Yersinia* and *Vibrio*, however, is a lethal event, although the reason is not known. In enterohemorrhagic *E. coli*, inactivation of the *dam* gene is also lethal due to the induction of a prophage in response to the increased level of SOS regulon expression. By contrast, inactivation of the *dam* gene in *Neisseria meningitidis* is not lethal and does not lead to a mutator phenotype, and inactivation of recombination does not lead to lethality. This suggests a fundamentally different role for Dam methyltransferase in this species compared to the *E. coli* paradigm.

The enterobacterial virus P1 has its own *dam* gene that is related to that of its *E. coli* host and is essential for its life cycle. Dam methylation is required at the stage where the viral DNA is packaged into the heads. This is accomplished by filling the head with genomic DNA and then cleaving it at specific sequences, termed *pac* sites. These *pac* sites are flanked by multiple GATC sequences which must be methylated in order for cleavage to occur. In other *E. coli* bacterial viruses, however, such as T2 and T4, deletion of the *dam* gene has no discernable effect on their life cycle. *Dam* genes are also present in certain

lambdoid bacteriophages but the essentiality of these genes in the viral life cycle has not yet been determined.

DNA Mismatch Repair and Homologous Recombination

I Matic, INSERM U1001, Université Paris Descartes, Paris, France

© 2013 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Ivan Matic and Miroslav Radman, volume 1, pp. 665–670, © 2004, Elsevier Inc.

Glossary

Homologous recombination Interaction between two DNA sequences sharing extensive nucleotide sequence identity, present on a single or two different DNA molecules, which results in a generation of mixed sequences derived from two parental ones. Such recombination events can be nonreciprocal (gene conversion or ‘patch’ recombinants) or reciprocal (crossover or ‘splice’ recombinants).

Meiosis (*meion*: smaller (Greek)) Two successive nuclear and cellular divisions resulting in the reduction of the chromosome number from diploid to haploid. The products

of meiosis are haploid gametes. As chromosome segregation in meiosis requires physical attachment of homologous chromosomes (chiasmata), each chromosome in the gamete is recombinant.

Mismatch The mispaired or unpaired bases in the double-strand DNA molecule.

Mitosis (*mitos*: thread (Greek)) The nuclear and cellular division of eukaryotic somatic cell resulting in generation of two daughter cells having the same number of chromosomes as the parent cell.

Mutation (*mutare*: to change (Greek)) Any heritable modification of genetic material.

Mismatches are mispaired or unpaired bases in the double-strand DNA molecule. Mismatches are generated as a consequence of errors during DNA replication or during homologous recombination involving nonidentical sequences. Specific mismatches can be formed by DNA damage. Enzymes that recognize and process mismatches have been identified in prokaryotes and eukaryotes. Different mismatch-repair systems (MRSs) are distinguished on the basis of their mismatch specificity and the size of excision tract that varies from single nucleotide to over a kilobase. The long-patch, also called the general, MRS (because it recognizes a variety of mismatches), is highly conserved during evolution. This molecular system maintains genomic stability by controlling fidelity of chromosomal replication by eliminating DNA biosynthetic errors and by controlling meiotic and mitotic homologous recombination. The control of homologous recombination is particularly important because this fundamental biological process is essential for the maintenance of chromosomal integrity, generation of genetic diversity, proper segregation of meiotic chromosomes, and speciation. In addition, MRS is required for activation of cell cycle arrest and apoptosis in response to certain types of DNA lesions, such as alkylation DNA damage. MRS also participates in transcription-coupled repair, in nonhomologous end joining (NHEJ) and in somatic hypermutation.

Specific mismatches created by chemical modification of DNA bases (e.g., G•T mismatch due to deamination of 5-methyl-C to T or 8-oxo-G•A mismatch due to oxidation of G) are repaired by specialized short-patch MRS. When such mismatches occur in the course of recombination, their localized repair in heteroduplex DNA creates mosaic sequences, that is, an apparent hyper-recombination effect (Figure 1).

Generalized MRSs

Escherichia coli Methyl-Directed Mismatch-Repair Pathway

The best-characterized, generalized MRS is *Escherichia coli* methyl-directed MRS. *E. coli* MRS, which has been completely

reconstituted *in vitro*, involves three dedicated proteins: MutS, MutL, and MutH. Other proteins that participate in processing of mismatches, DNA helicase II (UvrD), four exonucleases (Exo I, Exo VII, Exo X, and RecJ), SSB, DNA polymerase III holoenzyme, and DNA ligase, are shared with other repair pathways. MutS, protein recognizes and binds to a mismatch as a homodimer. The mismatch-binding domains of the two MutS proteins, although having identical amino-acid sequence, are structurally and functionally different. This indicates that the MutS homodimer–DNA complex is not symmetrical. Hence, the MutS homodimer acts as a functional heterodimer when bound to a DNA mismatch.

MutL homodimer associates with the MutS homodimer–mismatch complex, and recruits and activates MutH protein. MutH, which functions as a monomer and belongs to a family of type-II restriction endonucleases, incises the newly synthesized strand at a nearby hemi-methylated 5'-GATC-3' site. Hemi-methylated 5'-GATC-3' may reside either 3' or 5' to the mismatch at distances of, as much as, 1 kb or more. The N6 position of adenine in GATC sites is transiently not methylated in the newly synthesized strand, because methylation by Dam methylase lags behind replication by ~2 min. This strand-specific nick provides the initiation site for the mismatch-repair process and directs it to the newly synthesized strand. Neither MutH nor a nonmethylated strand is required if a single-strand break is present in the substrate DNA.

MutL also stimulates the loading and the processivity of UvrD at the mismatch-repair initiation site. UvrD unwinds the DNA duplex from the nick toward the mismatch, thereby allowing degradation of the displaced single-strand DNA, assuring the irreversibility of the repair process. The involvement of different single-strand-specific exonucleases in this repair pathway depends on orientation of the nick relative to the mismatch. Exo I or Exo X (3'→5' exonuclease), or Exo VII (3'→5' and 5'→3' exonuclease), or RecJ (5'→3' exonuclease) excises the nicked strand from the nicked site up to and slightly past the mismatch. The resulting single-stranded gap undergoes

Figure 1 Anti-recombination by long patch mismatch-repair system (LPMRS) and hyper-recombination by very short patch mismatch-repair system (VSPMRS). a/a', b/b', and c/c' represent single-nucleotide polymorphisms between two recombining DNA molecules (blue and red) (1). For simplicity, only one kind of strand exchange (asymmetric strand exchange) is shown; a:a', b:b', and c:c' are mismatched bases in the heteroduplex intermediate (2). LPMRS can destroy mismatched heteroduplex before (3) or after (4 and 5) resolution of recombination intermediates. Heteroduplexes that escape LPMRS, and which are sealed by ligase (6), will be separated by subsequent replication producing one recombinant and one parental DNA molecule. If some of the mismatches (e.g., b:b') in this heteroduplex molecule are substrate for VSPMRS, its activity will generate a complex recombinant on the repaired strand (7). Green lines represent tracts of DNA repair synthesis.

repair DNA resynthesis and ligation by DNA polymerase III holoenzyme, SSB, and DNA ligase. The excision-repair tracts associated with this pathway can be a kilobase long or longer. Hence, this repair system is referred to as the 'long-patch repair system.'

The critical first step in mismatch repair is the recognition and binding of MutS to mismatches. Detection of the mismatches, which are lacking the modified chemical groups generally present in most types of DNA damage facilitating their recognition, is a challenging task for the MutS protein. Binding affinities of MutS are about 10–1500-fold higher for mismatched than for perfectly matched DNA. Mismatch recognition by MutS is based on weakened base stacking of the mismatched base pairs and susceptibility to kinking rather than a specific shape or hydrogen-bonding pattern. Base pairing at the mismatch site undergoes significant reorganization upon MutS binding resulting in the 45–60° kink in the DNA helix.

MutS protein binds to seven of eight possible base pair mismatches. C●C mismatches, which are the least frequent replication error, are refractory. In addition, MutS protein binds up to four unpaired bases allowing for repair of frameshift errors. The affinities of MutS protein for various mismatches *in vitro* reflect the efficiency of the mismatch *in vivo*. Hence, transitions G●T et A●C, and transversions G●G et A●A, are repaired with the maximal efficiency. C●C are not repaired. Efficiency of the mismatch repair of transversions T●T, T●C et G●A depends on the local sequence context. The inactivation of *mutS*, or any other of *mut* genes coding for

general mismatch repair, results in strong identical mutator phenotypes with 10^2 – 10^3 -fold increased rates of transition and frameshift mutations.

MutS has an intrinsic ATPase activity, which actively dissociates MutS from DNA and performs a proofreading function to enhance mismatch-repair specificity. In the presence of homoduplex DNA, MutS quickly hydrolyzes ATP, but in the presence of a mismatch, the ATP hydrolysis is inhibited, which allows the MutS–DNA–ATP complex to form. Only when associated with both ATP and a mismatch is MutS able to recruit MutL protein. Thus, MutS uses ATP as a high-energy cofactor to compensate its low binding specificity and increase the repair specificity of the mismatch repair. Such kinetic proofreading ensures that interactions of mismatch-repair proteins with nonsubstrate DNA result in no repair.

Generalized Mismatch Repair in Eukaryotes

The knowledge about *E. coli* general MRS greatly facilitated identification and comprehension of homologous MRS in other organisms. Core MRS functions, MutS, and MutL proteins are conserved in almost all prokaryotes and eukaryotes. In eukaryotic organisms, invertebrates, vertebrates, and plants, multiple MutS and MutL homologs have also been identified. Different species contain different sets of homologs, without an obvious correlation to their position in the evolutionary tree. However, unlike their prokaryotic homologs, these proteins function as heterodimers. The most extensively characterized eukaryotic generalized MRS is that of *Saccharomyces cerevisiae*. In this organism, six MutS homologs (Msh 1–6) have been identified. Msh1 functions in mitochondria, while others act in the nucleus. Heterodimers of the MutS homologs cooperate with heterodimers of MutL homologs to process different mismatches. MutS α (Msh2–Msh6 heterodimer) complex recognizes base pair mismatches and insertions/deletions of one or two nucleotides. MutS β (Msh2–Msh3 heterodimer) binds to up to 12 nucleotides large insertion/deletion loops.

Four MutL homologs (Mlh 1–3 and Pms1) were identified in *S. cerevisiae*. Mlh2, Mlh3, and Pms1 proteins form heterodimers with Mlh1, which is a common subunit. These complexes are referred to as MutL α (Mlh1–Pms1 heterodimer), MutL β (Mlh1–Mv2 heterodimer), and MutL γ (Mlh1–Mlh3 heterodimer). The majority of mismatch-repair activity is carried out by MutL α interacting with either MutS α or MutS β complexes. MutL β and MutL γ have distinct specialized roles in the repair of mutational intermediates. As in prokaryotes, additional factors participate in *S. cerevisiae* mismatch repair: proliferating cell nuclear antigen (PCNA; processivity factor for replication machinery), Exo1 (5'→3' exonuclease), and the DNA polymerases δ and ϵ . The involvement of MutS and MutL homolog heterodimers was also observed in other eukaryotic organisms including humans.

There are some other significant differences between *E. coli* MRS and MRSs found in other organisms. In most organisms, DNA-strand recognition is not governed by DNA methylation. Dam methylase, coupled with the presence of *mutH* gene, has been identified in only a small number of bacterial species. The mechanism of strand discrimination in other prokaryotes and eukaryotes is not yet elucidated. However, a nick or a gap can serve as a signal that directs the reaction not only in *E. coli*, but

also in eukaryotic cells. This fact, together with the observation that mismatch repair is more efficient on the lagging strand than on the leading strand, suggest that DNA termini that occur as natural intermediates during replication may suffice as strand signals to direct the correction of DNA biosynthetic errors in eukaryotic cells.

Human and *S. cerevisiae* MutL α is a latent endonuclease that incises the discontinuous strand of a nicked heteroduplex in a mismatch- MutS α -, RFC-, PCNA-, and ATP-dependent manner. The activity of this endonuclease is dependent on the integrity of a DQHA(X)₂E(X)₄E metal-binding motif located within the C-terminal portion of PMS2. This motif is highly conserved in eukaryotic PMS2 homologs and is also common in archaeobacterial and eubacterial MutL proteins, but is lacking in MutL proteins from bacteria such as *E. coli* that rely on adenine methylation in 5'-GATC-3' sequences for strand discrimination during mismatch repair. Although *E. coli* MutH and human MutL are both latent endonucleases, these activities play functionally distinct roles in the two repair systems. Whereas MutH incision provides a nick, which serves as signal that directs repair, incision by MutL depends on preexistence of a signaling strand break.

MRS and Homologous Recombination

Anti-Recombination Activity in *E. coli*

Homologous recombination can be defined as interaction between two DNA sequences sharing extensive nucleotide sequence identity, present on a single or two different DNA molecules, which results in a generation of mixed sequences derived from two parental ones. The homologous recombination process occurs in four basic steps: initiation, homologous pairing and DNA exchange, DNA heteroduplex extension, and resolution. The recombination process is initiated by the combined action of a variety of nucleases and helicases that generate single-strand DNA. Single-strand DNA is a substrate for proteins that catalyze homologous pairing and DNA exchange. The best-studied homologous pairing and DNA-exchange protein is *E. coli* RecA.

RecA protein binds to single-strand DNA, or double-strand DNA containing single-strand DNA gaps, and forms a nucleoprotein complex containing one RecA protein monomer for every three nucleotides. RecA-single-strand DNA filaments engage in the search for homologous target DNA sequences. Scanning DNA for homologous sites is very fast and highly accurate even when they are very rare in the genome. *In vitro* data show that one helical turn of a RecA nucleoprotein filament, containing approximately six RecA monomers and 15 bases of single-strand DNA, is the functional unit sufficient to carry out the homology search. *In vivo* data show that RecA-catalyzed pairing is effective provided the length of shared uninterrupted identity is at least 26 nucleotides. This minimal effective DNA sequence identity required for homologous recombination is called the minimal efficient processing segment (MEPS).

After homologous pairing is achieved, the resultant joint molecules exchange homologous strands and establish heteroduplex DNA where each parental DNA contributes one complementary strand. Pairing of nonidentical DNA sequences produces mismatched heteroduplex molecules. RecA can detect

single mismatches at the initial stages of strand exchange, whose efficiency is strongly dependent on the location and distribution of mismatches. Mismatches near the 5' end of the incoming strand have a small effect, whereas mismatches near the 3' end strongly impede strand exchange. Once established, heteroduplex DNA is extended by a unidirectional branch migration step. At this step of recombination, RecA protein tolerates DNA lesions, large heterologies, and up to 30% nucleotide sequence divergence between recombining molecules.

MRS inhibits recombination between nonidentical DNAs as mismatched heteroduplex molecules are the substrate for MRS (Figure 1). MRS is capable of impeding recombination even between sequences with very low divergence, that is, less than 1%. While MRS inhibits recombination between DNAs differing by point substitution mutations and small insertions/deletions, it cannot prevent recombination between DNAs that have insertions/deletions >4 bp because resulting loops in heteroduplex molecules are not recognized by MRS. The MRS exerts anti-recombinogenic activity at different steps of homologous recombination. First, it acts as a fidelity element, which determines the length of MEPS by imposing an increased rigor during the homology search catalyzed by the RecA filament. Second, MRS blocks the RecA-catalyzed heteroduplex elongation, which results in the reversion of this step of homologous recombination. The increased concentration of RecA protein does not prevent mismatch-repair anti-recombination activity, whereas the overproduction of MutL protein severely reduces recombination frequency between nonidentical DNAs (Figure 2). Cellular MutL level is critical for the tolerance of base-pair mismatches in heteroduplex DNA. As MutL moderates the ATP-dependent dissociation of MutS from DNA, high concentration of MutL protein results in a longer sequestration of MutS protein on mismatches and therefore more effectively blocks the strand exchange process.

Unlike the identical effect of MRS mutants on spontaneous mutagenesis, the inactivation of different MRS genes has a distinct and characteristic effect on the recombination between nonidentical sequences. Very strong hyper-recombination effect is observed upon inactivation of *mutS* and *mutL* genes (Figure 2), while the effect of inactivation of *mutU* and *mutH* genes is relatively weak. The presence of single-strand ends in recombination intermediates (Figure 1) can explain the weak effect of *mutH* gene inactivation. The helicase II can probably be replaced by other enzymes that are involved in recombination, for example, RecG.

The anti-recombination activity of MRS in bacteria controls intergenomic gene transfer mediated by conjugation, transduction, and transformation. In addition, it controls intrachromosomal recombination between repeated, interspersed DNA sequences thus preventing potentially deleterious genomic rearrangements. For example, MRS reduces by 250-fold, recombination frequency between 96% identical repeated DNA sequences. Similarly, the frequency of intrachromosomal recombination between *E. coli* *rhsA* and *rhsB* loci (99% identical) increases 10–15-fold in *mutL* or *mutS* backgrounds. MRS also reduces the rate of gene conversion 1000-fold between <1% divergent *S. enterica* *tufA* and *tufB* genes. Gene conversion is a phenomenon in which genetic information on one chromosomal site is replaced with information from another site, which remain unchanged (nonreciprocal recombination).

Figure 2 The relationship between DNA sequence divergence, homologous recombination, and mismatch-repair system (MRS). Conjugational crosses between enterobacterial strains and species show that linear increase of sequence divergence between recombining genomes results in the exponential decrease in recombination frequency. This relationship shows that an increase in DNA divergence increases the difficulty for RecA protein to find the sites for initiation of homologous pairing and strand exchange. The MRS activity reduces the apparent length of these sites and blocking the maturation of RecA-catalyzed recombination intermediates. Consequently, the inactivation of MRS decreases the slope of correlation between recombination and DNA divergence, i.e., increasing the frequency of recombination between diverged sequences. By contrast, the overproduction of the key MRS proteins (MutS and MutL) increases the slope (MRS⁺⁺), i.e., creates new genetic barriers.

Therefore, the degree and distribution of sequence divergence between recombining DNA molecules are structural parameters that influence recombination efficiency because they affect the activity of recombination enzymes and determine whether the anti-recombinogenic activity of MRS proteins is triggered. Studies of the effects of DNA sequence divergence on the efficiency of homologous recombination show that there is an exponential decrease in recombination frequency with a linear increase in DNA divergence. This relationship results from an exponential decrease in the number of available MEPSs due to the requirements of RecA protein for the sequence identity. The slope of this relationship is determined by MRS activity, which alters MEPS size.

Anti-Recombination Activity in *S. cerevisiae*

Recombination between sequences at identical, allelic, positions on homologous chromosomes is important for mitotic DNA repair and for meiotic chromosome disjunction in eukaryotes. In addition to the allelic interactions, eukaryotic genomes contain large numbers of repeated sequences that can serve as substrates for nonallelic, ectopic, recombination events. Ectopic recombination can lead to alterations in genome structure and must be avoided as much as possible. As in bacteria,

recombination efficiency in eukaryotes depends on the DNA sequence identity and is controlled by different molecular mechanisms. Regulation of recombination in eukaryotes is best characterized in *S. cerevisiae*. In this organism, like in bacteria, recombination frequency decreases exponentially with a linear increase in DNA divergence between recombining DNA molecules. This log-linear relationship is due to the decrease of the number of MEPSs, which is estimated to be around 250 bp for *S. cerevisiae*. Mismatched recombination intermediates are substrate for MRS in *S. cerevisiae*, where it inhibits recombination between nonidentical DNA sequences both in mitosis and in meiosis. Even a single mismatch in heteroduplex molecule is sufficient for MRS to inhibit recombination. Additional mismatches have a cumulative negative effect on recombination efficiency. When DNA sequence divergence reaches several percent, the probability of a heteroduplex recombination intermediate escaping detection by the MRS is so low that the additional mismatches fail to increase anti-recombination activity. The MutS α or MutS β complexes recognize the same types of mismatches in recombination intermediates as in replication intermediates. Although *msh2* and *mlh1* or *pms1* mutants have identical mutator phenotypes, *msh2* mutants exhibit higher recombination rates between nonidentical DNAs than do *pms1* or *mlh1* mutants. This indicates that Msh binding to mismatch may by itself inhibit the recombination process.

In *S. cerevisiae*, MRS processing of recombination intermediates results in gene conversion or in complete destruction of recombination intermediates. In *S. cerevisiae*, where it is possible to analyze all four products derived from a single meiosis, a non-Mendelian 3:1 segregation pattern of allelic sequences is diagnostic of a gene conversion event. In the absence of a functional MRS, mismatches in heteroduplex recombination intermediates are not repaired and the mismatch-containing DNA strands segregate at the first mitotic division following meiosis (postmeiotic segregation or PMS). The frequency of PMS reflects the repair efficiency for the particular mismatch. In *msh2*, *pms1*, *mlh1*, and, to a lesser extent, *msh3* and *msh6* mutants, meiotic gene conversion events are reduced while PMS events are elevated. Since the repair patch is shorter than the meiotic heteroduplex DNA, the repair process does not necessarily interfere with the formation of crossing-overs. MRS also inhibits crossing-overs between diverged chromosomes in interspecific hybrids during meiosis, and is therefore important for establishing and maintaining interspecific genetic barriers as well.

Although the same mismatch-repair machinery detects mismatches in both recombination and replication intermediates, some accessory proteins are unique to each type of repair. For example, PCNA appears to play a role in correcting DNA replication errors, but has not been implicated in the correction of heteroduplex recombination intermediates. In addition, two *S. cerevisiae* MutS homologs, Msh4 and Msh5, have completely lost the ability to participate in a standard mismatch-repair reaction, but have acquired novel, meiosis-specific roles. The loss of either MSH4 or MSH5 is associated with an approximately 50% reduction in meiotic crossing-over, in increased levels of homolog nondisjunction, and decreased viability of meiotic products. The Msh4 and Msh5 genes are in the same epistasis group and, like the other MutS homologs, physically interact to form heterodimers. As gene

conversion levels are normal in *msh4* or *msh5* mutants, the Msh4–Msh5 complex is assumed to act late in recombination. Genetic data indicate that the Msh4–Msh5 heterodimer interacts specifically with the Mlh1–Mlh3 complex to promote meiotic crossing-over. Both *mlh1* and *mlh3* mutants exhibit a reduction in meiotic crossover events, and epistasis analysis indicates that Mlh1 and Msh4 act in the same crossover pathway. Interestingly, mitotic recombination in yeast is more sensitive (in a mismatch-repair-dependent manner) to low levels of sequence divergence than is meiotic recombination, which may help reinforce the strong bias for sister chromatid versus interhomolog interactions during mitosis.

MRS was also shown to play an important role in inhibition of ectopic interactions between nonidentical, repetitive DNA sequences, during both mitosis and meiosis, and hence maintain genome stability by preventing genome rearrangements. Single-strand annealing (SSA) is a major recombination pathway for repairing spontaneous and induced double-strand breaks that arise between repeated sequences. Annealing of complementary single-stranded DNA molecules produced by the exonucleolytic processing of double-strand breaks adjacent to repetitive genomic sequences produces a variety of branched DNA structures including the 3' tails at the junction of double-stranded and single-stranded DNA. Msh2–Msh3 heterodimer binds to these structures and stabilizes them, thus allowing the removal of nonhomologous DNA tails by structure-specific nuclease, Rad1–Rad10.

During SSA, the requirement for Msh2–Msh3 depends upon the length of the annealed region. Rad1–Rad10-dependent 3' end processing requires Msh2–Msh3 only when the annealed region is lesser than 1 kb. Decreased dependence on Msh2–Msh3 is also observed with larger loop sizes during Rad1–Rad10-dependent meiotic loop repair. Msh2 physically interacts with both Rad1 and Rad10 independently of other mismatch-repair factors, and no other mismatch-repair factors are required for Rad1–Rad10-dependent 3' end processing, besides Msh3. Msh2 localizes to double-strand break sites flanked by nonhomologous sequence, and Msh2 and Msh3 physically interact with subunits of the single-strand binding protein RPA. The role of Msh2–Msh3 in nonhomologous tail removal during recombination can be distinguished from its role in DNA mismatch repair, as mutations have been isolated in *MSH2* that disrupt mismatch repair but are functional for recombination.

DNA Sequence Divergence, Mismatch Repair, Loss of Heterozygosity, and Cancer in Mammals

Except for the mitochondrial Msh1 protein, all other *S. cerevisiae* MutS and MutL proteins are present in mammalian cells. Defects in MRS in mammals are associated with genome-wide instability, predisposition to certain types of cancer, including hereditary nonpolyposis colorectal cancer, resistance to certain chemotherapeutic agents, and abnormalities in meiosis and sterility. Carcinomas evolve by accumulation of several somatic mutations, of which some are recessive (e.g., in tumor suppressor genes). Such mutations are expressed only when homozygous, that is, when both alleles in diploid cells are inactivated by mutation. The passage from the heterozygous (*m/+*) to

homozygous (*m/m*) or hemizygous (*m/o*) state usually occurs by a chromosomal rearrangement leading to the loss of the functional gene copy (Figure 3). Such rearrangement can be due to (1) the loss of the (+) allele (e.g., a small or large deletion, or the loss of the entire chromosome) or (2) a homologous recombination event, such as gene conversion, of the allele to (*m/m*) or a mitotic crossover anywhere between the centromere and the allele (Figure 3). All these events, with the exception of gene conversion, lead to the loss of heterozygosity (LOH), initially present because of the maternal/paternal sequence divergence (about 0.1% of nucleotides in human population).

Two lines of experiments suggest that the functionally largely neutral sequence polymorphism between the two parental lines effectively suppresses the mitotic recombination mechanism for LOH:

1. Gene targeting in mouse embryonic stem cells is highly sensitive to the natural sequence polymorphism of the parental strains. This suppression of mitotic recombination can be relieved by the defect in mismatch repair, that is, it appears that the mammalian mismatch-repair acts to prevent mitotic recombination between nonidentical sequences.
2. The expression of a recessive heterozygous (*m/+*) mutation in inbred, globally highly homozygous mice, occurs at elevated frequency *via* mitotic recombination, that is, LOH from the crossover point to the end of the chromosome

Figure 3 DNA sequence divergence, mismatch repair, and loss of heterozygosity. Only one pair of homologous chromosomes is shown. The chromosome colors (blue and green) indicate the sequence polymorphism between the maternal and paternal line (0.1% in human population). The symbol (*m*) stands for a specific recessive mutation. Only cells (*) having lost the wild type (+) allele express the (*m*) mutation. Such cells show loss of heterozygosity (LOH; yellow). In human tumors, most LOH occurs by chromosomal rearrangements (top right). However, in inbred mice, with little or no sequence divergence between homologs, most LOH occurs by mitotic recombination. The recombination-suppressing effect of sequence polymorphism is relieved in MRS-deficient mouse cells (see Figure 1). Because LOH is an obligate step in the expression of recessive mutations in tumor suppressor genes, sequence polymorphism protects against cancer due to MRS activity.

including the recessive mutation (Figure 3). In hybrids between different strains, the LOH frequency is much lower than in inbred strains. The decrease in LOH is accounted by the loss of mitotic recombination due to the activity of the MRS.

Thus, it appears that, like in bacteria and *S. cerevisiae*, recombination in mammals has same requirements for DNA sequence identity. Increase of sequence divergence between recombining DNA molecules reduces recombination efficiency by decreasing the number of available MEPSs and by the anti-recombination activity of MRS. MEPSs in mammalian cells was estimated to be about 250 bp. Such genetic barriers based on the genomic sequence polymorphism are expected to (1) delay the process of carcinogenesis by delaying the expression of relevant recessive somatic and inherited mutations and (2) enhance sympatric speciation by creating genetic isolation on the germline level.

Evolutionary Role of the Control of Homologous Recombination by Mismatch Repair

Evolutionary conservation of key MRS functions illustrates the importance of this genetic system in the preservation of genomic integrity in prokaryotes and eukaryotes. In bacteria, the loss of MRS activity can provide transient selective advantage when adaptation is limited by the supply of mutations. However, the restoration of MRS proficiency is a prerequisite for evolutionary success because upon adaptation, the load of deleterious mutations is no longer counterbalanced by the generation of beneficial mutations resulting in fitness reduction. In eukaryotes, the increased genomic instability resulting from MRS deficiency is apparently never advantageous. For example, in mammals, the loss of MRS activity is associated with male and female sterility and tumorigenesis.

Increased frequency of chromosomal rearrangements is a deleterious phenotype of MRS deficiency in prokaryotes and eukaryotes. The MRS-mediated recombination surveillance is particularly important for eukaryotes because their genomes contain a multitude of repetitive DNA sequences. MRS in *S. cerevisiae* prevents intra- and interchromosomal crossovers and gene conversions resulting from recombination between nonidentical DNA sequences.

By controlling homologous recombination, MRS also controls the process of speciation. In bacteria, MRS controls conjugational, transductional, and transformational recombination between strains and species, thus reducing gene flow between diverged populations. Similarly, by controlling crossing-over and chromosome segregation in meiosis, MRS prevents hybridization between diverged organisms resulting in reproductive isolation of closely related species.

Glossary

Apoptosis An active cell death process that requires RNA and protein synthesis to specifically digest cellular DNA into nucleosomal fragments; it is also known as programmed cell death.

Cytotoxicity The degree to which an agent possesses a specific destructive action on certain cells or the possession of such action; it is often used when referring to the action of antineoplastic drugs that selectively kill dividing cells.

DNA mismatch Non-G:C or -A:T DNA base pairs or small insertion/deletion (unpaired) nucleotides in duplex DNA; it is also called a heteroduplex.

DNA mismatch repair A DNA repair pathway that specifically converts mismatched DNA bases (heteroduplexes) into normal G:C or A:T base pairs (homoduplexes).

Tumorigenesis The process that generates tumors.

DNA mismatches are base-pairing errors that deviate from the Watson–Crick rules that stipulate that A pairs with T and G pairs with C. In addition, small insertion/deletion structures, in which one DNA strand contains a small number of unpaired nucleotides, are also considered mismatches. Mismatched base pairs occur as errors during the normal course of DNA replication and recombination, and they are mutagenic if left uncorrected. DNA mismatch repair (MMR) is a cellular process that rectifies mismatches to yield correct Watson–Crick base pairs. MMR is an important genome maintenance system because defects in the system cause genome-wide instability and have been implicated in the development of certain types of human cancer. In the past, the ability of the MMR system to correct DNA heteroduplexes has been considered the primary mechanism by which it contributes to genomic stability. However, more recent studies indicate that the MMR system also contributes to genomic stability by mediating protective cellular responses to DNA damage.

MMR Proteins and Their Role in Mismatch Correction

The eukaryotic MMR pathway is similar to the *Escherichia coli* MthLS pathway with respect to features of mechanism and involvement of several homologous activities. In fact, many of the eukaryotic MMR components were initially identified by their sequence homology to the *E. coli* MMR proteins (see Table 1). The eukaryotic MMR proteins are known to include the MutS homologs (MutS α and MutS β), the MutL homologs (MutL α , MutL β , and MutL γ), exonuclease I (ExoI), replication protein A (RPA), a eukaryotic SSB (single-strand DNA-binding protein), and DNA polymerase δ . Although eukaryotic homologs of the bacterial MthH and helicase II have not yet been identified, studies in human nuclear extracts have demonstrated that the human MMR reaction possesses a mechanism similar to that of *E. coli*, that is, the repair is targeted to the newly synthesized strand and can occur bidirectionally. The eukaryotic system appears, however, to be more complex than the *E. coli* pathway. For example, whereas there is

only a single form of MutS or MutL in *E. coli*, at least two MutS homologs and three MutL homologs have been identified in eukaryotic cells, each of which is a heterodimer. For example, MutS α consists of the polypeptides MSH2 and MSH6, and MutL α comprises MLH1 and PMS2 (see Table 1). These MutS and MutL heterodimers, although redundant, play special roles in MMR subpathways. In human cells, MutS α and MutL α are the most abundant species among the MutS and MutL heterodimers, respectively.

MMR Function Is Required for Drug Cytotoxicity

Although MMR is well known for its role in correcting biosynthetic errors, recent studies have revealed another important role that the MMR system plays in genome maintenance, that is to mediate DNA damage signaling programmed cell death (or apoptosis).

Treatment of cells with chemical DNA-damaging agents, such as the alkylating agents *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG), temozolomide, and procarbazine, leads to increased amounts of cell death. For this reason, these cytotoxic agents are often used in chemotherapy to kill rapidly growing tumor cells. Interestingly, it has been found almost universally that, whereas cells that are proficient in MMR are sensitive to these agents, cells that are deficient in MMR are more resistant to killing by these agents. This was first observed with *E. coli* in the 1980s when *E. coli* MMR mutants (*mutS*[−] or *mutL*[−]) were found to be more resistant to killing by MNNG than were wild-type bacterium. Subsequently, resistance to these alkylating agents was observed in human cells that are defective in MutS α or MutL α . An interesting example is afforded by the development of the lymphoblastoid cell line MT1. This cell line was derived from the TK6 cell line by selection with a high dose of MNNG. MT1 cells are 500-fold more resistant to killing by this agent than the parental cells and exhibit an elevated spontaneous mutation rate. The MT1 cell line was subsequently found to be defective in *MSH6*, the gene that encodes a subunit of MutS α . Conversely, many human

Table 1 MMR components and their function^a

<i>E. coli</i>	Human	Function
MutS	MutS α (MSH2-MSH6) ^b	DNA mismatch/lesion sensor
MutL	MutS β (MSH2-MSH3) MutL α (MLH1-PMS2) ^b MutL β (MLH1-PMS1) MutL γ (MLH1-MLH3)	Molecular chaperon, endonuclease, and excision terminator
MutH	Not identified	Strand discriminator
Helicase II	Not identified	Unwinding DNA helix
ExoI, ExoVII, ExoX, RecJ	ExoI	Removing mispaired base
Pol III holoenzyme	Pol δ , PCNA	Repair DNA synthesis
SSB	RPA	Protecting template DNA from degradation
DNA ligase	DNA ligase I	Nick ligation

^bMajor components in cells.

tumor cells that are defective in MMR have been found to be relatively resistant to alkylating agents. For example, the *MLH1*-defective HCT116 colorectal tumor cell line is resistant to killing by MNNG, but its MNNG-resistant phenotype is lost after the cell line received a wild-type copy of the *MLH1* gene by chromosome transfer. Therefore, the cytotoxicity of DNA-damaging agents depends on a functional MMR system.

MMR Proteins Promote DNA Damage-Induced Cell-Cycle Arrest and Apoptosis

Normal cells are known to undergo growth arrest at cell-cycle checkpoints when exposed to DNA-damaging agents. This response allows cells to respond to DNA damage either by repairing the damage or by committing programmed cell death (apoptosis). Interestingly, cells defective in MMR fail to arrest at crucial checkpoints after exposure to DNA-damaging agents. For example, MMR-proficient cells undergo growth arrest at the G2 phase of the cell cycle after treatment with alkylating agents, but MMR-deficient cells do not. The G2 phase arrest in MMR-proficient cells has been found to be associated with apoptosis. As illustrated in **Figure 1**, when wild-type TK6 cells and MutS α -deficient MT1 cells were treated with MNNG, apoptotic cell death was observed in TK6 cells (see the pattern of DNA fragmentation, a classical characteristic of apoptosis), but not in MT1 cells. Similarly, MutL α is also required for alkylating agent-induced apoptosis. This MMR-dependent apoptotic response can also be induced by other DNA-damaging agents, including cisplatin, certain environmental carcinogens, and ionizing radiation. In addition to cell lines, DNA-damage-induced MMR-dependent apoptosis also occurs in classic laboratory animals such as the mouse and the soil nematode *Caenorhabditis elegans*.

How is the MMR pathway involved in the apoptotic response? Although the details are far from clear, it has been established that the mismatch recognition proteins (i.e., MutS α

Figure 1 MNNG induces apoptosis in MMR-proficient cells.

MMR-proficient TK6 and MMR-deficient MT1 cells were treated with MNNG for 1 h and then cultured in fresh medium for 72 h before harvesting. Genomic DNAs isolated from MNNG-treated (+) and untreated cells (–) were electrophoresed in a 2% agarose gel and detected by UV-illumination in the presence of ethidium bromide. Notice that DNA fragmentation is observed in MNNG-treated TK6 cells, but not in MNNG-treated MT1 cells. This DNA fragmentation pattern is diagnostic of apoptosis, or programmed cell death.

and MutS β) recognize DNA bases damaged or modified by a variety of agents. These agents include MNNG, cisplatin, chemical carcinogens, oxidative free radicals, and ultraviolet (UV) light. These damaged DNA bases, or DNA adducts, possess structures different from regular bases, thereby causing conformational changes in the DNA duplex. For example, whereas the 8-hydroxyguanine adduct generated by ionizing radiation is approximately the same size as guanine, the guanine adduct of benzo[a]pyrene dihydrodiol epoxide, an environmental chemical carcinogen, is twice as large as guanine. However, a common feature shared by these DNA adducts, as well as DNA base–base mismatches, is that they more or less distort the structure of the DNA helix. This distortion may constitute the basis of their recognition by MutS proteins.

MMR Proteins Interact with Proteins Involved in DNA Damage Signaling

It is generally accepted that DNA damage response requires at least three types of components: damage sensors (ataxia telangiectasia, mutated (ATM), ATM and Rad3-related (ATR), and the Rad9–Rad1–Hus1 (9–1–1) complex), signal transducers (Chk1 and Chk2), and effectors (p53 and p73). Recent studies have implicated all these three components in MMR-dependent damage signaling. First, MutS α and MutL α physically interact with ATR, ATM, and the 9–1–1 complex, and these interactions activate ATR and ATM kinases to phosphorylate Chk1 or Chk2, which phosphorylates downstream components such as p53 and p73. Second, phosphorylation and stabilization of both p53 and p73 occur in an MMR-dependent manner during cellular response to MNNG- or cisplatin-induced DNA damage. These observations indicate that MMR-dependent apoptosis in response to DNA damage involves a signaling cascade, and that MMR proteins (MutS α and MutL α) are the initiator of the signaling cascade.

MMR-Mediated Apoptosis Eliminates Damaged Cells from Tumorigenesis

The molecular events involved in the MMR-dependent apoptotic response have not yet been established. However, based on what is already known, the apoptotic signaling is initiated by binding of MMR proteins to DNA adducts. Two models have been proposed to describe the role of MMR in DNA damage signaling (Figure 2). The futile cycle model (Figure 2, left) proposes that repetitive attempts by MMR to remove a DNA adduct in the template DNA strand cause cell death. DNA adducts in the template strand can pair with appropriate bases or lead to mispairs during DNA replication. MutS α , along with MutL α , recognizes these unusual base pairs as mismatches and provokes a strand-specific MMR reaction. However, because MMR is always targeted to the newly synthesized strand, adducts in the template strand cannot be removed and thus unusual base pairs re-form upon DNA resynthesis during repair. As a result, the repair cycle can be perpetually reinitiated. Such a futile repair cycle may signal cells to switch on apoptotic machinery. An alternative model, referred to as 'the direct signaling model' (Figure 2, right), suggests that the death signal could directly come from the binding of MutS α and MutL α to DNA adducts in the replication fork. These protein–DNA adduct complexes may block DNA transactions such as replication, transcription, and repair and could be recognized as a signal for cell-cycle arrest and death. In both models, the action on DNA adducts by MMR proteins activates DNA damage signaling cascade by activating ATR or ATM protein kinase and its downstream transducers and effectors, leading to apoptosis (Figure 2).

The MMR pathway is well known for its function of promoting genomic stability. The newly identified apoptotic function of MMR, however, may be as important as its replication-fidelity function for maintaining genomic stability. Normally, base excision repair and nucleotide excision repair pathways are responsible for the repair of DNA damage induced by physical and chemical agents. However, when excision repair pathways are not available or there is too much damage to be repaired, genomic DNA is in danger of accumulating a large number of mutations, a process that is tumorigenic. Eliminating these damaged cells from the body would be beneficial. It is the MMR system that initiates the elimination of these pretumorigenic cells by promoting apoptosis. The inability of the

Figure 2 Proposed models of how MMR mediates apoptosis in response to DNA damage. The futile repair cycle model (left) suggests that DNA adducts (solid black circle) induce misincorporation, which triggers the strand-specific MMR reaction. Since MMR only targets the newly synthesized strand for repair, the offending adduct in the template strand cannot be removed, and will provoke a new cycle of MMR upon repair resynthesis. Such a futile repair cycle persists and activates the ATR and/or ATM damage signaling network to promote cell-cycle arrest and/or apoptosis. The direct signaling model (right) proposes that recognition of DNA adducts by the MutS α –MutL α complexes allows the proteins to recruit ATR and/or ATM to the site, activating the downstream damage signaling. Modified from Li GM (2008) Mechanism and functions of DNA mismatch repair. *Cell Research* 18: 85–98.

MMR system to commit genetically damaged cells to apoptosis may contribute to a molecular basis for cancer development.

DNA Mismatch Repair in Bacteria

A-L Lu, University of Maryland, Baltimore, MD, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Base excision repair (BER) A DNA repair pathway that is initiated by a DNA glycosylase to remove relatively small lesions. Some glycosylases are highly specific to certain lesions or mismatches.

dam methylation The methylation of the adenine at the 6-NH₂ group in GATC sequences by *dam* methylase. Methylation on the parental strands and transient unmethylation on the newly synthesized strands provide a signal to direct the mismatch repair to the daughter strands.

Mismatch repair (MMR) A process in which the long-patch MMR removes replicative errors that are missed by DNA polymerase's proofreading activity. MMR also functions during genetic recombination and corrects certain types of DNA damage.

Mutator phenotype A phenotype that is associated with elevated genomewide spontaneous mutation frequencies and is usually caused by mutations at the DNA repair genes.

Replication fidelity The extremely low error rate of DNA replication, which is achieved by the accuracy of DNA replication and mismatch repair.

There are two major DNA mismatch-repair (MMR) systems in bacteria to correct DNA biosynthetic errors. Long-patch repair systems involve a long-patch excision and resynthesis (up to 1000 nucleotides) and are specific to a particular DNA strand. Short-patch repair systems have a repair tract shorter than 15 nucleotides, and are dictated by the nature of the mismatches. The methyl-directed MMR distinguishes the daughter strand from the parental strand by the hemi-methylated state of the DNA and enhances the fidelity of DNA replication and genetic recombination. Cells defective in MMR have several hundred-fold higher spontaneous mutation frequencies of transitions and short nucleotide insertion/deletion mutations. MMR-defective strains are resistant to some types of alkylating agents. MMR also has an anti-recombination function in limiting recombination between divergent sequences and preventing gross chromosomal rearrangement. The short-patch MutY base excision repair (BER) pathway is independent of methylation. MutY, an adenine DNA glycosylase, is responsible for the reduction of replication errors caused by oxidized guanines (8-oxoGs). MutY pathway may be coupled with DNA replication and cooperate with the mismatch repair pathway to achieve anti-mutagenic functions.

Escherichia coli Long-Patch Mismatch Repair Is Dependent on *dam* Methylation

For MMR to correct replication error, a strand-discrimination system must target the repair to the daughter DNA strand that contains the incorrect nucleotides. *Escherichia coli* MMR is dependent on DNA adenine methylation (*dam*) and is biased to the unmethylated DNA strand. The *dam* methylase modifies the adenine at the 6-NH₂ group in GATC sequences. In 1976, Wagner and Meselson proposed that transient undermethylation of GATC sites in newly synthesized DNA provides the basis to direct the MMR to the daughter strands, an idea that has been confirmed both *in vivo* and *in vitro*. As methylation is a postsynthetic process, methylation on the parental strands and transient unmethylation on the newly synthesized strands provide the

signal to direct the repair to the daughter strands. MMR can be directed by hemi-methylated sites located either 5' or 3' to the mismatch at a separation distance of up to 1 kb. Some bacteria and eukaryotes lack adenine methylation and may use strand break on the daughter strands as a discrimination mechanism. MMR that occurs during genetic recombination is also independent of DNA methylation. MMR has an anti-recombination function in limiting recombination between divergent sequences and preventing gross chromosomal rearrangement. It has been shown that MMR plays a vital role in preventing interspecies recombination between *E. coli* and *Salmonella typhimurium*.

Specificity of Mismatch Repair

Methyl-dependent MMR has a broad specificity. Of the eight possible base-base mismatches, only C-C is refractory to the repair. Heteroduplexes containing short insertion/deletion loops (IDLs) (up to five unpaired nucleotides) derived from DNA polymerase slippage can also be repaired. The efficiency of MMR is influenced by the sequence flanking the mismatch. The MMR system has also been shown to be involved in the repair of oxidative DNA damage. The major oxidative lesion, 7,8-dihydro-8-oxo-guanine (8-oxoG, G^o), can mispair with adenine during DNA replication. *E. coli* MMR can remove either adenine or G^o on the daughter strand from the A-G^o mispairs. MutS can also recognize O⁶-methyl-guanine (O⁶-meG) paired with T, U-G mispair, ultraviolet (UV) photoproducts, and cisplatin adducts. The efficiency of lesion recognition by MutS is not proportional to the repair efficiency.

Mechanism of *E. coli* Long-Patch Mismatch Repair

An *in vitro* assay developed by Lu and colleagues has provided the basis for purifying and characterizing the *E. coli* MMR proteins. The *E. coli* MMR pathway has been reconstituted *in vitro* from purified proteins in P. Modrich's laboratory. Biochemical and genetic studies have shown that *E. coli* MMR

Table 1 Functions of *E. coli* mismatch repair enzymes

Enzyme	Function
MutS	DNA mismatch/damage recognition
MutL	Molecular matchmarker; enhances mismatch recognition; stimulates MutH, UvrD, DNA polymerase III, and the β clamp activities
MutH	Strand discrimination; cleaves at unmethylated DNA strands
UvrD	DNA helicase II; unwinding DNA
ExoI, ExoX	3' to 5' exonuclease; removes nucleotides
ExoVII, RecJ	5' to 3' exonuclease; removes nucleotides
DNA Pol III	DNA resynthesis of the long-patch mismatch repair pathway
holoenzyme	A subunit of DNA Pol III holoenzyme; interacts with MutS and MutL
β sliding clamp	Protecting DNA from degradation and re-anneal
SSB	Nick ligation
DNA ligase	DNA glycosylase; excises A from A/G, A/8-oxoG, A/C, and A/5-hydroxyuracil mismatches and removes G from G/8-oxoG mismatches
MutY	Endonuclease; removes T from T-G mismatch
Vsr	Repair synthesis of short-patch mismatch repair and base excision repair pathways
DNA polymerase I	

requires 11 protein activities: MutS, MutL, MutH, UvrD (DNA helicase II), four single-strand specific exonucleases, a single-strand DNA-binding protein (SSB), DNA polymerase III (Pol III) holoenzyme, and DNA ligase (Table 1). Whereas MutH, MutL, and MutS are specific for MMR, the other proteins are involved in other DNA metabolic pathways, including replication and recombination. The mechanism of *E. coli* long-patch MMR is depicted in Figure 1.

Initiation of Mismatch Repair

MMR requires specifically MutH, MutL, and MutS proteins in the initiation steps. The first step of MMR is the recognition of mismatches by the MutS protein. MutS recognizes base–base mismatches and short IDLS. MutL serves to couple mismatch recognition by MutS to activate several downstream activities. MutH endonuclease cleaves at the 5' of G of an unmethylated GATC sequence at the transiently hemi-methylated GATC sites. This ensures that MMR is directed to the newly synthesized DNA strands.

MutS

MutS (a 95-kDa polypeptide) exists as an equilibrium of dimers and tetramers and recognizes all base–base mismatches except C–C mismatch and small IDLS up to five unpaired nucleotides. The discrimination of a mismatch-containing heteroduplex from a homoduplex by MutS protein is not great; there is only 10–20-fold preference. It has been suggested that mismatch recognition by MutS may be enhanced by MutL or by the association with replication proteins such as β -clamp. MutS is a member of the ABC transporters with adenosine triphosphatase (ATPase) activity, which is activated by DNA and is essential for the MMR function. ATP binding reduces the MutS affinity for heteroduplex DNA. Although several models have been proposed, the role of ATPase of MutS is still under

investigation. The translocation and sliding clamp models suggest that MutS moves away from the mismatch site to activate MMR. The translocation model suggests that ATP hydrolysis provides the energy and enables MutS to move like a motor protein. The sliding clamp model or molecular switch model suggests that ATP-bound MutS slides along DNA without ATP hydrolysis. There is a conformational change from adenosine diphosphate (ADP)-bound MutS to ATP-bound MutS. The third model suggests that the ATPase activity of MutS plays a kinetic proofreading role in MMR. In the presence of a mismatch, ATP hydrolysis is inhibited and MutS recruits downstream repair proteins to the sites. The co-crystal structures of MutS–DNA–ADP suggest that MutS has to bind both ATP and the mismatched DNA simultaneously to activate the repair process. Thus, the model suggests that MutS remains bound to the mismatch site and recruits MutL and MutH to initiate MMR.

The structures of truncated forms of *E. coli* and *Thermus aquaticus* MutS proteins complexed with unpaired or mispaired bases have been solved by both T. Sixma and W. Yang's groups. Although different types of mismatches were used, all MutS structures are very similar. These structures show that MutS homodimer forms an oval disk with two channels, one of which encircles the DNA at the mismatch. The bound DNA is sharply kinked by 60° toward a narrowed major groove at the mismatch. The minor groove of DNA is widened and contacted extensively by MutS. Interestingly, MutS forms an asymmetric dimer with only one monomer making direct contact with the mismatched base. MutS contacts the mismatched bases through a highly conserved N-terminal motif Phe–X–Glu. The Phe residue in this conserved motif is inserted into the double helix via the minor groove and stacks with a mismatched base. The ATP-binding site at the C terminus (domain V) of the protein is composed of residues from both subunits and is located far from the DNA-binding site. Domains II and III connect the mismatch-binding and ATPase domains. In the absence of DNA, the mismatch-binding domains (domains I and IV) are disordered in the crystal structure. The extreme C-terminus of MutS, which is not present in the structural studies, has been shown to be important for mutation avoidance, tetramer formation, and dimer stability.

MutL

MutL is a dimer of a 68-kDa polypeptide that operates as a molecular matchmaker in MMR to assemble a functional repair complex. MutL plays a key role in determining biological outcome by recruiting and/or activating downstream proteins in response to lesion recognition by MutS. In the presence of ATP, MutL binds to the MutS–heteroduplex complex and activates MutH endonuclease, UvrD helicase, DNA Pol III, and the β clamp activities. MutL can bind nonspecifically to DNA and this DNA binding is essential for MMR. Studies on a ternary complex consisting of MutS–MutL–mismatched DNA show that MutL increases the DNaseI footprint of MutS–mismatched DNA. The divergent C-terminal domain of MutL is responsible for the dimer formation in solution. The conserved N-terminal domain has weak ATPase activity that is stimulated by single-stranded DNA. The structures of both domains have been determined and both domains are predicted to be linked by a random coil. Structural and biochemical studies indicate that ATP binding and hydrolysis modulate the conformation,

Figure 1 The long-patch methyl-dependent mismatch-repair system of *E. coli*. Mismatches (G–T, as shown) are recognized by dimeric MutS protein. After binding of MutL and MutH, the unmethylated strand in red is nicked by MutH at the hemi-methylated GATC sites (M in yellow circle represents for methyl groups). ATP hydrolysis by MutS and MutL triggers the downstream repair process. DNA unwinding by UvrD (DNA helicase II) in the presence of ATP from the nick site toward the mismatch reveals a single-stranded DNA region that is protected by SSB. Depending on the position of the nick relative to the mismatch, ExoVII or RecJ with 5' to 3' exonuclease activity and ExoI, ExoVII, or ExoX with 3' to 5' exonuclease activity degrade the nicked strand from the nick site up to and slightly past the mismatch. The resulting single-stranded gap undergoes repair resynthesis by the DNA Pol III holoenzyme and the nick is finally sealed by DNA ligase. Open arrows represent the direction of exonuclease degradation and thick green arrows show the direction of repair resynthesis.

oligomeric state of MutL, and the interactions of MutL with its partners. Upon ATP binding, the N-terminal domain undergoes conformation changes and dimerizes. In addition to function in MMR, MutL also interacts with enzymes involved in nucleotide excision repair (UvrB and UvrC), BER (MutY), and very short patch (VSP) (Vsr) pathways. C. G. Cupples proposed that stalled MutS–MutL complex may recruit these partners to the lesion sites.

MutH

The 25-kDa monomer MutH belongs to a family of type II restriction enzyme. MutH protein is absent in bacteria without *dam* methylase. MutH endonuclease activity is activated by MutS and MutL in the presence of ATP and a mismatch-containing DNA. W. Yang has proposed that MutS and MutL facilitate MutH binding to hemi-methylated DNA and overcome the inhibition of MutH by SegA (the competitor for MutH). MutH cleaves at the 5' side of the G of the GATC sequence on unmethylated strand located on either the 5' or 3' side of the mismatch. Tyr212 of MutH is important in sensing the methylation status of DNA. The structure of MutH is like a clamp with a cleft and two arms. In the complex of MutH with hemi-methylated GATC substrate, the active site is more compact and DNA cleavage is more efficient than that

of MutH complexed with unmethylated substrates. The Lys residue in the conserved DEK motif is the linchpin that couples DNA cleavage with sequence-specific recognition.

Excision and Repair Synthesis of Mismatch Repair

The strand break created by MutH at a GATC site of the unmethylated strand serves as the starting point for excision of the mispaired base. MutL interacts with and stimulates UvrD helicase, and facilitates the loading of the helicase on the nick. UvrD unwinds DNA from the nick toward the mismatch and reveals a single-stranded DNA region that is protected by SSB.

The excision of the displaced strand is then initiated from the nick by one or more of the exonucleases and is dependent on MutS, MutL, and UvrD. Depending on the position of the nick relative to the mismatch, ExoVII or RecJ with 5' to 3' exonuclease activity and ExoI, ExoVII, or ExoX with 3' to 5' exonuclease activity degrade that portion of the nicked strand displaced by the helicase up to and slightly past the mismatch (within 100 nucleotides). The resulting single-stranded gap is filled in by the DNA Pol III holoenzyme, and the nick is finally sealed by DNA ligase. MMR may be coupled with DNA replication via physical interactions of MutS and MutL with the β -clamp, the processivity factor for DNA Pol III.

Mismatch Repair Deficiency and Drug Resistance

The MMR proteins not only repair replication errors but also recognize or repair lesions that arise from DNA damage. Tolerance to methylating agents and cisplatin was observed in MMR-deficient *E. coli* and eukaryotic cells. This finding has significant impacts on drug sensitivity of cancer patients undergoing chemical therapy. *E. coli* *dam* mutant is sensitive to killing by these agents and this sensitivity is lost when *mutS* or *mutL* mutation is introduced. The mechanism of killing has been proposed by the formation of double-strand breaks generated by activated MutH on both unmethylated DNA strands. The pathway leading to cell killing in *E. coli* seems to be different from those in mammalian cells.

MutY Repair Pathway

In addition to the long-patch methyl-dependent MMR, two short-patch MMR pathways have been characterized in *E. coli*. Only the MutY repair pathway is described here and the VSP pathway initiated by Vsr endonuclease is covered elsewhere in this encyclopedia.

Oxidative damage is a major source of mutation load in living organisms. G° is one of the most stable products of oxidative DNA damage and has the most deleterious effects because it can mispair with adenine. In *E. coli*, MutT, MutM (Fpg), Nei (EndoVIII), MutS, and MutY are involved in defending against the mutagenic effects of G° lesions (Figure 2). The MutT protein eliminates 8-oxo-dGTP from the nucleotide pool with its pyrophosphohydrolase activity (Figure 2, reaction 1),

whereas the MutM glycosylase removes G° from G° -C base pairs. MutS and MutY increase replication fidelity by removing the adenines misincorporated opposite G° or G during DNA replication (Figure 2, reaction 3). Nei can excise G° from G° -C or G° -A and serve as a backup pathway to repair G° in the absence of MutM and MutY. When dGTP is incorporated opposite adenine during DNA replication, MutY repair on G° -A can cause more mutation (Figure 2, reaction 5) while G° -A repair by MutS and Nei can reduce mutation (Figure 2, reaction 6).

The *E. coli* MutY protein is a 39-kDa DNA glycosylase that removes a free base from DNA to initiate BER process. Although MutY can form a covalent Schiff base intermediate with its DNA substrates, it is controversial whether MutY has AP lyase (β -elimination) activity in addition to the DNA glycosylase activity. MutY specifically excises mispaired adenines from A-G, A- G° , A-C, and A-5-hydroxyuracil mismatches and removes guanines from G- G° mismatches. The DNA-binding affinity of MutY with G- G° is similar to that of A- G° , but the catalytic activity of MutY to G- G° is much weaker than that to A- G° . MutY binds tightly to noncatalytic DNA containing T- G° and C- G° . A- G° mismatches are particularly important biological substrates for MutY. MutY, like other DNA glycosylases, binds tightly to its DNA product containing an apurinic-apyrimidinic (AP) site. This prevents the release of toxic AP intermediates and the formation of double-strand breaks. It has been suggested that BER pathway may involve highly coordinated processes. The MutY BER pathway involves DNA PolI and DNA ligase and may involve AP endonuclease (EndoIV or ExoIII). MutY also interacts with Nei (EndoVIII) glycosylase. EndoIV, ExoIII, and Nei enhance the product

Figure 2 8-oxoG repair in *E. coli*. The MutT protein hydrolyzes 8-oxo-dGTP (d G° TP) to 8-oxo-dGMP (d G° MP) and pyrophosphate (reaction 1). The MutM glycosylase (Fpg protein) removes mutagenic 8-oxoG (G°) adducts (structure is shown in the inset) while they are paired with cytosines (reactions 2, 4, and 7). Nei can function as a backup for MutM. When C-8-oxoG is not repaired by MutM, adenines are frequently incorporated into the 8-oxoG bases during DNA replication. MutS and MutY increase replication fidelity by removing the adenines misincorporated opposite 8-oxoG (reaction 3). When d G° TP is incorporated opposite adenine during DNA replication, MutY repair on G° -A can cause more mutation (reaction 5) while G° -A repair by MutS and Nei can reduce mutation (reaction 6). MutY repair is coupled with DNA replication and MutS-dependent MMR to ensure repair fidelity. Adapted from Bai H and Lu A-L (2007) Physical and functional interactions between *Escherichia coli* MutY glycosylase and mismatch repair protein MutS. *Journal of Bacteriology* 189: 902–910, with permission from American Society for Microbiology.

release with A–G but not with A–G° substrates. Thus, it remains unclear how MutY dissociates from AP–G° *in vivo*.

The most frequent mutations observed in *mutY* mutants are G–C to T–A transversions (~50-fold higher than the wild-type cells). The *mutY* mutants also have slightly increased G–C to C–G and G–C to A–T mutations due to the defects in G–G° and A–C (or A–5-hydroxyuracil) repair, respectively. The *mutM* and *mutT* mutants have approximately 20-fold and 1000-fold higher mutation frequencies than wild-type cells, respectively. However, the mutation rate of *mutY* and *mutM* double mutants is about 1000-fold higher than the wild-type cells. By contrast, *mutY* and *mutT* double mutants have twofold lower mutation frequency than the single *mutT* mutants.

MutY glycosylase contains a [4Fe–4S] iron–sulfur cluster and it belongs to a conserved helix–hairpin–helix (HhH) family that includes several DNA glycosylases. The X-ray crystal structure of the N-terminal catalytic domain of *E. coli* D138N–MutY with bound adenine shows that adenine is buried in the active site of the catalytic domain, suggesting that the mismatched adenine must flip out of the DNA helix for the glycosylase action. The iron–sulfur cluster loop is important in substrate recognition and MutY stability, and the HhH motif is involved in binding to the phosphate backbone. The structure of MutY from *Bacillus stearothermophilus* in complex with A–G°-containing DNA was determined. Similar to several DNA glycosylases, MutY distorts the bound DNA and flips out the mismatched adenine out of the helix but the mismatched G° remains intrahelical. The C-terminal domain of MutY has been shown to play an important role in the recognition of G° lesions. The C-terminal domain of MutY has no homology to other members of the HhH superfamily, but shares structural similarities to MutT. The N-terminal catalytic domain and the C-terminal domain are connected through a flexible linker. The intact MutY encircles the bent DNA. It has been proposed that MutY scans the DNA cooperatively as a dimer or a multimeric complex to locate mismatches.

To be successful in repairing the replication errors caused by G°, MutY adenine glycosylase activity must be directed to the newly synthesized DNA strand. If MutY activity targets the adenines on the template DNA strand, A–T to C–G transversions will arise (Figure 2, reaction 5) and the repair would be mutagenic. The mechanisms that modulate the MutY glycosylase activity and allow it to target only newly synthesized DNA remain elusive. It has been suggested that coupling to DNA replication and interacting with MutS ensure that MutY BER is targeted to the daughter DNA strands but not to the parental strands. *E. coli* MutY has been shown to interact with the β -clamp and mismatch repair enzymes (MutS and MutL) (see later). A similar mechanism is also suggested in the human MutY homolog (MYH or MUTYH) repair because MYH interacts with proliferating cell nuclear antigen (PCNA), replication protein A (RPA), and MutS homologs.

Similarity and Interaction between MutS and MutY Repair Pathways

MutS-dependent MMR and MutY repair pathways share many common features. First, both pathways take place immediately after DNA replication to increase the fidelity of DNA

replication. To do so, both pathways need to distinguish daughter strands from parental strands. Both pathways may be coupled with DNA replication because MutS, MutL, and MutY interact with the β -clamp. Second, both pathways recognize base–base mismatches such as A–G and A–C. Finally, both pathways are responsible for reducing mutations caused by oxidative damage. MutY removes misincorporated adenines from A–G° while *E. coli* MMR prevents oxidative mutagenesis by removing either adenines or G° from A–G° mispairs. Wyrzykowski and Volkert have shown that when MMR-defective cells are grown anaerobically, spontaneous mutation frequencies are reduced compared with those of the same cells grown aerobically. In addition, a *dam* mutant has an increased sensitivity to hydrogen peroxide treatment. This sensitivity can be suppressed by mutations that inactivate MMR. Although the most frequent mutations observed in *mutS* mutants are A–T to G–C and G–C to A–T transitions, overexpression of MutS protein significantly decreases the rate of G–C to T–A transversions in wild-type, *mutY*, and *mutM* mutants. Thus, the MMR and MutY pathways have extensively overlapping functions.

It has been shown that *E. coli* MutS interacts with MutY by stimulating the DNA-binding activity of MutY with A–G° mismatches. Further, the expression level of MutY is upregulated in *mutS* cells as compared with the wild-type cells. Unexpectedly, the frequency of A–T to G–C mutations is reduced by two- to threefold in a *mutSmutY* mutant as compared to a single *mutS* mutant. Our data suggested a cooperation and competition model for the MutS–MutY interaction. In MutS⁺ cells, A–C mismatches generated during DNA replication are mainly repaired by MutS-dependent mismatch repair. MutS enhances MutY binding to A–G° mismatches. In *mutS* cells, MutY is overproduced to repair A–G° mismatches. However, when MutY activity is increased in the *mutS* cells to excise adenines on both daughter and parental strands, it may cause A–T to G–C transitions and A–T to C–G transversions (Figure 2, reaction 5). An alternative explanation for the decreased mutagenesis in the *mutSmutY* strain as compared to the *mutS* mutant is that MutS enhances the strand specificity of MutY. C. G. Cupples' group has also shown that MutL interacts with MutY. Overall, these findings suggest that the MutY repair pathway may cooperate with the MMR pathway to achieve anti-mutagenic functions.

DNA Mismatch Repair in Disease and Aging

P Hsieh, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

DNA polymerase Enzymes that synthesize DNA using one strand as a template to direct synthesis.

Epigenetic silencing The inhibition of gene expression caused by methylation of DNA sequences in the promoter region of genes.

Microsatellite instability (MSI) The accumulation of frameshift mutations in simple repeat sequences found in most eukaryotic chromosomal DNA.

Mispaired base An incorrectly pair base in DNA, for example, a G paired opposite T, or an unpaired base resulting from incorporation of an extra base during DNA replication.

MutL Bacterial mismatch repair (MMR) protein that interacts with MutS to initiate MMR; equivalent proteins that

are conserved in eukaryotic cells are MutL homologs (MLHs).

MutS Bacterial MMR protein that recognizes mismatched DNA and interacts with MutL; equivalent proteins that are conserved in eukaryotic cells are MutS homologs (MSHs).

Proliferating cell nuclear antigen (PCNA) A ring-shaped protein that keeps proteins like DNA polymerases bound to DNA.

Replication protein A (RPA) Protein complex that binds to single-strand DNA and facilitates DNA synthesis.

Tumor suppressor gene Gene whose product prevents the development of a tumor. These genes become inactivated by mutation during tumor development.

Introduction

DNA replication is normally a highly faithful process with mutations occurring at a frequency of only one in 10^9 – 10^{10} base pairs (bp) per cell division. This fidelity is maintained by three equally important processes, nucleotide selection at the active site of the DNA polymerase, the exonucleolytic proof-reading function of the polymerase, and DNA mismatch repair (MMR) functioning in a post replication fashion. The MMR pathway is highly conserved from bacteria to humans, and its loss universally confers a mutator phenotype. Early observations of a hypermutator phenotype in model microorganisms presaged the discovery in humans that mutations in MMR genes confer a heritable predisposition to colorectal cancer in which tumor cells exhibit a hypermutator phenotype. DNA MMR targets two classes of replication errors, base–base mispairs, for example, when G is misincorporated opposite T, and loops of unpaired bases that result when the template strand of the DNA slips out of alignment with the new strand that is being synthesized. If uncorrected, base–base mispairs give rise to missense mutations while loops give rise to frameshifts. Mismatches can also arise during homologous recombination, a process whereby genetic information is transferred between maternal and paternal chromosomes during meiosis, and as a result of exposure to DNA damaging agents. In this article, the consequences of loss of MMR for disease and aging are discussed.

Molecular Mechanisms of DNA Mismatch Repair

The first step in MMR is the recognition of mismatches by MutS proteins (see [Figure 1](#)). How MutS proteins find relatively rare DNA mismatches poses interesting problems as there are few chemical signatures that can serve as flags for their location. In addition, while mismatch binding by MutS proteins can be

sensitive to the DNA sequence immediately adjacent to the mismatch, so-called sequence context effects, MutS proteins find mismatches without relying on a specific DNA sequence. In prokaryotes, there is a single MutS protein that functions as a homodimer. In eukaryotes, this is the role of the MutS homologs or MSH proteins so called because they are similar in structure and function to the bacterial MutS proteins. MSH2–MSH6, referred to as MutS α , is a heterodimeric protein that recognizes base–base mispairs as well as small loops of one or a few bases. MutS β , MSH2–MSH3, preferentially targets loops. All MSH proteins are members of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter superfamily of ATPases, and each heterodimeric protein has two composite nucleotide-binding sites built from amino acid residues contributed by both protein subunits. Binding and hydrolysis of adenosine triphosphate (ATP) serve to effect conformational changes that modulate both protein–DNA and protein–protein interactions. Structural and biochemical studies reveal that MutS α forms a clamp on a mismatched DNA whose interaction with the mismatch is modulated by the nucleotide cofactors ATP and adenosine diphosphate (ADP). Both MSH6 and MSH3 interact with proliferating cell nuclear antigen (PCNA), a protein required for DNA synthesis, via a conserved motif at the amino-terminus of the MSH proteins. PCNA, which forms a tripartite ring that encircles the DNA, appears to facilitate recruitment of MutS α to mismatched DNA.

A second critical participant in MMR is the MutL protein. Here again, bacteria have a homodimeric MutL protein. In eukaryotes, there are multiple MutL homologs that function as heterodimeric proteins, but the primary MMR protein in mammalian cells is a heterodimer of MLH1–PMS2 known as MutL α . All eukaryotic MutL homologs like their bacterial counterparts have an essential ATPase activity, and ATP binding and hydrolysis again play important roles in modulating the activity of MutL α . Structural studies indicate that MutL α is a very dynamic protein like MutS α , and undergoes large

Figure 1 Cartoon Scheme for Eukaryotic DNA Mismatch Repair. Recognition of a mismatch by MutS α (MSH2–MSH6) or MutS β (MSH2–MSH3, not shown) and MutL α (MLH1–PMS2) results in the formation of a ternary complex whose protein–protein and protein–DNA interactions are modulated by ATP/ADP cofactors (indicated by red *) bound by MutS α (or MutS β) and MutL α . PCNA, a DNA replication factor, may help recruit MMR proteins to the vicinity of the advancing replication fork. Nicking by the endonuclease function of PMS2 stimulated by ATP, PCNA and RFC (symbolized by green arrows) must target the excision step to the newly synthesized strand. Excision by EXO1 in concert with PMS2 gives rise to a DNA duplex having a single-strand gap coated with RPA in which the mismatched nucleotide(s) have been excised. Resynthesis by the replicative POL δ and sealing of nicks by DNA ligase restore the integrity of the duplex. Adapted from Hsieh P and Yamane K (2008) DNA mismatch repair: Molecular mechanism, cancer, and ageing. *Mechanisms of Ageing and Development* 129: 391–407, with permission from Elsevier.

conformational changes during the course of repair. In bacteria, MutL interacts with and stimulates proteins such as DNA helicases, proteins that separate DNA strands, and exonucleases that carry out subsequent excision steps of MMR. Such protein–protein interactions are also thought to be mediated by MutL α though the exact mechanism is unknown.

The formation of a ternary complex consisting of MutS α , MutL α , and a mismatched DNA signals the start of the excision step of MMR. Details of how this ternary complex is formed and its overall architecture remain subjects of intense study. In the presence of ATP, MutS α is a sliding clamp that can diffuse away from the mismatch. *In vitro* studies of MutS and MutL bound to

mismatched DNAs suggest that multiple MMR proteins are loaded on the DNA in the vicinity of the mismatch. Although details are still missing, it is clear that both MutS α and MutL α are required to authorize the start of excision.

Excision of the mismatch in the newly synthesized DNA strand followed by gap filling by a replicative DNA polymerase and ligation complete the MMR pathway and yield an intact DNA duplex free of any replication errors. The development of *in vitro* MMR assays reconstituted with purified proteins has led to the identification of proteins required for MMR. Excision initiates at a nick in the newly synthesized DNA strand positioned on either side of the mismatch. In *Escherichia coli*, the single-strand breaks are made by the MutH endonuclease that nicks at specific methylated sequences in the *E. coli* chromosome. MutH targets the newly synthesized strand for breakage because having just been synthesized, it is temporarily missing the methylation modification unlike the fully methylated parental strand. In most other bacteria and in all eukaryotes, there is no MutH protein or corresponding DNA methylation signal to confer strand discrimination. In these organisms, MMR may utilize nicks that originate during the normal DNA replication process. For example, in the lagging strand, DNA synthesis is discontinuous leading to the formation of short Okazaki fragments that are separated by transient gaps. These gaps could serve to prime MMR. Whatever the origin of the initiating nicks, these must direct excision to the newly synthesized strand rather than the parental or template strand.

EXO1, a 5′–3′ double-strand DNA exonuclease, can utilize nicks on the 5′ side of a mismatch and is, to date, the only exonuclease that has been shown to be required for MMR. Excision from the 3′ side remained an enigma until it was discovered that PMS2, one of the two subunits of MutL α , harbors a cryptic endonuclease activity. This endonuclease activity is stimulated by the replication factor C (RFC) and PCNA, proteins that facilitate normal DNA synthesis. How PMS2 directs nicking exclusively to the newly synthesized strand is unclear at present. Thus, the combined nuclease activities of EXO1 and MutL α can explain bidirectional excision though it is still possible that other as yet unidentified proteins participate. The intermediate that is formed, a DNA duplex containing a single-strand gap coated with the single-strand DNA-binding protein RPA, is then a substrate for DNA synthesis by Pol δ aided by PCNA, a protein that improves the efficiency of DNA synthesis and RFC, a protein that loads PCNA onto DNA. In the final step, DNA ligase seals the nicks.

DNA Mismatch Repair and Cancer

The worldwide incidence of colorectal cancer is estimated at over a million cases annually. Of these, Lynch syndrome, or hereditary nonpolyposis colorectal cancer, constitutes approximately 3–5% of all colorectal cancer cases making it the most prevalent inherited colorectal cancer predisposition syndrome. Heterozygous germline mutations in the DNA MMR genes *MSH2* and *MLH1* account for the majority of Lynch syndrome families. Less common are mutations in *MSH6* and *PMS2*. Tumors result when the remaining functional copy of an MMR gene is inactivated via somatic mutation or loss of heterozygosity (LOH) giving rise to an autosomal

dominant mode of inheritance. In addition, it is estimated that approximately 15% of all spontaneous cases of colorectal cancer are characterized by microsatellite instability (MSI), a hallmark of MMR deficiency. MSI refers to contractions and expansions of regions of the genome containing simple nucleotide repeats, for example, a run of A's or repeating (AT)_n. These can occur due to frameshift mutations that accumulate in the absence of MMR as these simple repeats are prone to slippage during replication and misalignment of the template DNA strand with respect to the newly synthesized strand.

Evidence to support the idea that cancer can develop from increased mutation rates due to uncorrected replication errors stems from several findings. First, mutations in MMR genes cause Lynch syndrome. Second, approximately 15% of tumors in the case of sporadic colorectal cancer exhibit MSI at mono-, di-, tri-, and, more rarely, tetra-nucleotide repeats, and these tumors are associated with epigenetic silencing of *MLH1*, the gene encoding an MutL protein. Such epigenetic silencing results from hypermethylation of DNA bases in the promoter region of *MLH1*. Third, laboratory mice harboring disruptions of MMR genes exhibit MSI and a marked predisposition to cancer. How do high mutation rates contribute to cancer? In individuals who have lost MMR activity, genes that normally inhibit tumorigenesis, for example, tumor suppressor genes, may be inactivated, particularly if they harbor simple nucleotide repeats that are prone to contraction or expansion. Other genes, oncogenes, that are normally turned off in healthy tissue, may become activated or acquire a tumor-promoting function as a result of mutation.

Clinical studies of families with frequent diagnoses in multiple generations of colorectal cancer without polyposis as well as gastric and uterine cancer led to agreement on a set of criteria for diagnosing hereditary nonpolyposis colorectal cancer (HNPCC) known as the Amsterdam Criteria and Amsterdam Criteria II. Subsequently, the Bethesda Guidelines were developed to aid in identifying colorectal cancer (CRC) patients who should be tested. Molecular genetics studies of affected families led to the identification of cancer susceptibility loci mapping to specific regions on human chromosomes 2 and 3. The discovery of specific defects in MMR genes was achieved when it was appreciated that tumor cells from Lynch syndrome patients exhibited the same kind of DNA MSI as that found in microorganisms like *E. coli* and budding yeast that were missing MMR. Thus, germline mutations first in *MSH2* and *MLH1* and then in *MSH6* and *PMS2* were discovered.

The diagnosis of Lynch syndrome requires careful attention to family histories and documentation of all cancers in family members. Although the syndrome is defined by mutations in MMR genes, direct determination of inactivating mutations in MMR genes is not routinely done in the colorectal cancer population at large. Clinically, there is no specific list of phenotypic features, but notable features include the frequent occurrence of colorectal cancer in families, an autosomal dominant inheritance pattern, a relatively early age of onset, on average 45 years of age compared to the mid-60s in the normal population, a tendency toward proximal (right-sided) colonic cancer, and strikingly, the presence of a variety of extracolonic tumors including heightened risk of endometrial and ovarian cancer in females (see Table 1). The pathology of colorectal cancer is oftentimes poorly differentiated with an excess of

Table 1 Cardinal features of Lynch syndrome (LS)

Autosomal dominant inheritance pattern seen for syndrome cancers in the family pedigree
Earlier average age of colorectal cancer (CRC) onset than in the general population
Average age of 45 years in LS vs. 69 years in the general population
● Proximal (right-sided) colonic cancer predilection
<70% of LS CRCs are proximal to the splenic flexure
Accelerated carcinogenesis (tiny adenomas can develop into carcinomas more quickly)
Within 2–3 years in LS vs. 8–10 years in the general population
High risk of additional CRCs
25–30% of patients having surgery for an LS-associated CRC will have a second primary CRC within 10 years of surgical resection if the surgery was less than a subtotal colectomy
Increased risk for malignancy at certain extracolonic sites ^a
Endometrium (40–60% lifetime risk for female mutation carriers)
Ovary (12–15% lifetime risk for female mutation carriers)
Stomach (higher risk in families indigenous to the Orient, reason unknown at this time)
Small bowel
Hepatobiliary tract
Pancreas
Upper uro-epithelial tract (transitional cell carcinoma of the ureter and renal pelvis), especially in males with LS-MSH2 type ^b
Brain (in the Turcot's syndrome variant of the LS)
Multiple sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas in the Muir-Torre syndrome variant of LS
Pathology of CRCs is more often poorly differentiated, with an excess of mucoid and signet-cell features, a Crohn's-like reaction, and a significant excess of tumor-infiltrating lymphocytes within the tumor
Increased survival from CRC
The sine qua non for diagnosis is the identification of a germline mutation in a mismatch repair gene (<i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> , or <i>PMS2</i>) that segregates in the family: that is, members who carry the mutation show a much higher rate of syndrome-related cancers than those who do not carry the mutation

infiltrating lymphocytes within the tumor. Individuals with Lynch syndrome are at very high risk for developing colorectal cancer necessitating intensive surveillance including regular colonoscopies starting in the mid-20s.

As discussed earlier, instability at microsatellite sequences is a hallmark for the loss of MMR. Currently, most Lynch syndrome candidates with suggestive family histories undergo MSI testing according to the Revised Bethesda Guidelines. These guidelines include (1) a diagnosis of colorectal cancer in individuals <50 years of age; (2) the presence of synchronous or metachronous colorectal, or other syndrome-associated tumors regardless of age; (3) colorectal cancer with microsatellite instability-high (MSI-H) diagnosed in a patient who is <60 years

of age; (4) colorectal cancer or syndrome-associated tumor diagnosed under age 50 years in at least one first-degree relative; and (5) colorectal cancer or syndrome-associated tumor diagnosed at any age in two first- or second-degree relatives. Syndrome-associated tumors include sebaceous adenomas, sebaceous carcinomas, and multiple keratoacanthomas associated with Muir-Torre syndrome and primary brain tumors associated with Turcot syndrome.

Following the Bethesda Guidelines, a panel of five microsatellite markers is surveyed, three with dinucleotide repeats and two with mononucleotide repeats. When two or more of these five show a change in the number of repeats in tumor tissues compared with normal tissues, this is classified as MSI-H. Approximately 20–25% of these tumor cells have mutated MMR genes. Alteration at only one of the five

microsatellite sequences is termed MSI-low and is not associated with germline mutations in MMR genes. Immunohistochemistry can be used to detect the levels of MMR proteins in tumor cells using antibodies to MSH2, MSH6, MLH1, or PMS2. In the case of MSH2, loss is usually via deletion and immunohistochemistry can readily reveal its absence. Loss of MSH2 protein also reduces the amount of MSH6 protein as this subunit appears to be unstable without MSH2. In contrast to MSH2, most Lynch syndrome mutations in *MLH1* are missense mutations in which the protein is produced, but not functional. In this case, immunohistochemistry can be uninformative. For those individuals who are MSI-H, germline mutation testing is recommended. Recent advances in technology make DNA sequencing for direct detection of germline mutations and DNA methylation much more feasible. Efforts

Figure 2 Structural model for human MutS α with HNPCC mutations. Four views of MutS α related by 90° rotations as indicated, with positions of HNPCC missense mutations indicated by spheres. Hypothetical functional classification of mutations is indicated by sphere color (see legend). MSH2 and MSH6 are shown as light and dark gray C α chain traces, respectively, and the DNA is colored orange. Three clusters of surface mutations, which may correspond to sites of protein-protein interactions are indicated with dashed ovals. Reproduced from Warren JJ, Pohlhaus TJ, Changela A, et al. (2007) Structure of the human mutS α DNA lesion recognition complex. *Molecular Cell* 26: 579–592, with permission from Elsevier.

are underway to improve diagnostic sequencing with regard to both sensitivity and cost.

Individuals with tumor cells classified as MSI-H tend to have better clinical prognoses overall and are less likely to benefit from adjuvant chemotherapy. Why MSI-H is associated with a better outcome is unclear, but the poor response to adjuvant chemotherapy may reflect the role of MMR proteins in the cellular response to DNA damage. A subset of DNA-damaging agents commonly used in chemotherapy are incorporated into DNA or chemically modify DNA bases and result in cell killing. In this way, tumor cells that are rapidly dividing are targeted for elimination. Examples of cytotoxic DNA modifying drugs include Temozolomide that adds a methyl group to DNA bases and flurouracil that is metabolized to fluorodeoxyuridine and incorporated into DNA. The cytotoxicity of these drugs requires functional MutS α and MutL α proteins. The noncanonical bases resulting from drug treatment cause the DNA polymerase to make errors during DNA synthesis leading to the formation of mispairs that are recognized by MutS α . Subsequently, cells arrest at strategic points in the cell cycle and activate apoptotic or programmed cell death pathways. Understanding how this happens is an area of active research. Since MSI-H cells with inactivating mutations in MSH2 or MLH1 lack MutS α or MutL α , the cytotoxic effects of these chemotherapeutic drugs may be compromised. A related issue in chemotherapy is the observation that tumors oftentimes become tolerant to treatment. The chemotherapy regimen exerts selective pressure on cells that are missing MMR. Examination of these tumor cells reveals that expression of the *MLH1* gene has been silenced by hypermethylation.

What regions of MutS α are important for its tumor suppressor function? X-ray crystallographic studies of bacterial and human MutS and MutL proteins have revealed the three-dimensional (3D) structure of these proteins with atomic resolution. One can map mutations found in Lynch syndrome/HNPCC patients that change only one amino acid residue onto representations of the 3D structure of MMR proteins. These are shown in [Figure 2](#) for human MutS α (MSH2–MSH6) bound to a mismatched DNA. It is immediately obvious that mutations that lead to cancer map all over the MutS α molecule, in all the structural domains, in regions that are at the surface, and in those that are buried. Based on structure–function studies of MMR proteins, one can surmise that HNPCC mutations can disrupt many different aspects of MMR. They can interfere with critical protein–protein interactions, alter the stability of the proteins, disrupt ATP binding or hydrolysis or interfere with DNA binding. Disease-causing mutations are invaluable in helping investigators to understand how proteins carry out their normal function and what happens when that function is disrupted. In the best scenarios, they can also direct efforts at finding new treatments.

Other Aspects of MMR in Disease and Aging

DNA MMR proteins have important roles in a number of cellular functions. It is not surprising, therefore, that inactivation or loss of these proteins has important implications for health. In the examples that follow, it is important to note that unlike Lynch syndrome where mutations in MMR genes

resulting in the loss of MMR have unequivocally been established as an underlying cause of cancer, the roles of MMR in other disease processes is inferential and has been studied almost exclusively in model experimental systems such as yeast, mouse models, and cultured human cells. These studies reveal novel functions of subsets of MMR and suggest that MMR proteins can, in certain contexts, assume functions that are quite distinct from post replication MMR.

A special case of DNA repeat instability involving repeats of specific DNA triplets causes human neurological and muscular inherited diseases such as Huntington's disease and myotonic dystrophy. The most common trinucleotide repeats implicated in disease are CAG, CTG, CCG, and GAA triplets. In unaffected individuals, the number of triplet repeats is stable. However, in affected individuals, the repeat is unstable and expands. The expanded sequence can disrupt protein or RNA expression and/or function leading to disease. In studies utilizing a mouse model having long CTG repeats, MSH2, MSH3, and PMS2, but not MSH6, appear to have an ameliorating effect on triplet expansion. The underlying mechanism is unclear at present though it is certain to involve many other processes. Work proceeds to understand repeat instability and the evolutionary importance of the repeats themselves with the goal of eventually finding therapeutic approaches.

Eukaryotic versions of bacterial MutS and MutL proteins have diverged and some now function exclusively in meiosis, a key step in sexual reproduction. The product of meiosis is haploid gametes that have only one of the two sets of chromosomes found in diploid cells. Fertilization involving male and female gametes restores the full chromosome complement. These gametes are formed in a specialized program of cell divisions that exactly halves the number of chromosomes in daughter cells. In mice that have been genetically ablated for two meiosis-specific MutS homologs, *MSH4* or *MSH5*, or for the MutL homologs, *MLH1* or *MLH3*, meiosis is arrested, and the animals are by and large infertile. Thus, the MSH4–MSH5 and MLH1–MLH3 proteins are required to carry out meiosis and appear to ensure the proper alignment and separation of paired chromosomes so that the chromosome number can be reduced by exactly half. Since these MMR proteins are conserved in humans as well, it is quite likely that they have important roles in human sexual reproduction though that remains to be confirmed.

Some MMR proteins also have functions in the generation of immuno-globulins or antibodies that function in the immune response. In most mammals, this process occurs in specialized lymphocytes in bone marrow called B cells. Paradoxically, in B cells the MMR proteins participate in a hypermutation process that stands in marked contrast to post replication repair where MMR proteins serve to keep mutations in check. Antibodies must recognize and bind a vast array of antigens and carry out different immune functions. Vertebrates create antibody diversity by combining different short protein segments in a combinatorial process of immunoglobulin assembly, but they also require a hypermutation phase. Studies of immunoglobulins in mice missing different MMR proteins indicate that MSH2–MSH6 and EXO1 are important for somatic hypermutation, and mice missing MSH2, MSH6, or EXO1, and to a lesser extent, MLH1 and PMS2, exhibit reduced repertoires of different immunoglobulin. In all these cases, the bulk of the evidence suggests

that MMR proteins are functioning in alternative pathways to canonical post replication MMR.

The accumulation of DNA damage and resulting genomic instability not only cause cancer but are thought to be contributors to aging as well. Does loss of MMR contribute to aging? This question is difficult to address as neither Lynch syndrome patients nor MMR-deficient mice show overt signs of premature ageing. However, some studies of mouse models suggest that the capacity for MMR diminishes with age, and MMR can process certain types of oxidative DNA damage that are thought to accumulate with age. In addition, data from budding yeast and mice suggests that loss of MLH1 and/or PMS2 can increase cell proliferation in special cases. The role of DNA repair in aging remains an active area of research.

Summary

DNA MMR plays a critical role in preserving the integrity of the genome in virtually all organisms. Loss of MMR proteins MSH2, MLH1, PMS2, and MSH6 lead to greatly elevated rates of mutation, and, in humans, a genetic predisposition to cancer. MMR proteins also modulate responses to DNA damaging agents that are common chemotherapeutic drugs. Studies of model organisms point to important roles for subsets of MMR proteins in trinucleotide repeat expansion diseases, sexual reproduction, and immunoglobulin diversity, and the role of MMR in the aging process remains unclear. Much work remains to understand how the MMR proteins function in so many diverse processes and to find new therapeutic avenues.

Glossary

ATP (adenosine triphosphate) A nucleotide that serves as a source of energy for physiological reactions and as a protein cofactor for a variety of processes.

ATPase Enzymatic activity associated with protein molecules and accompanied domains that hydrolyze ATP into ADP, releasing inorganic phosphate.

DNA polymerase Enzymatic activity that catalyzes the synthesis of DNA using a template DNA molecule, a primer, and deoxyribonucleotides.

DNA repair Reconstruction of an intact double-stranded DNA molecule free of damage or mismatches by a variety of enzymatic processes.

DNA replication The process of DNA synthesis that creates an identical copy from a template DNA molecule.

Endonuclease Enzymatic activity that cleaves the phosphate backbone of single- or double-stranded DNA at interior positions within a polymer.

Excision DNA repair process that removes part of a damaged DNA strand generally through the directed activity of exonucleases.

Exonuclease Enzymatic activity that removes individual nucleotides from the 3' or 5' ends of single- or double-stranded DNA polymers.

Indel mutations Insertion/deletion loops that arise from slippages that occur when DNA polymerase is replicating repetitive sequences in the genome.

Mismatch DNA base interactions that do not follow the classical Watson–Crick G–C or A–T pairing rules.

Mutation A change in a DNA sequence that can occur from a variety of unrepaired endogenous or exogenous insults.

Introduction

Mismatch repair (MMR) is an evolutionarily conserved pathway comprising components that work in concert to recognize DNA polymerase-mediated misincorporation errors and facilitate their excision. These misincorporations are primarily base–base mismatches (e.g., G–T, C–A) or insertion/deletion loops (indels) that arise from slippages that occur when DNA polymerase is replicating repetitive sequences in the genome (Figure 1). The major MMR components, Mut proteins, were identified several decades ago in the bacterium *Escherichia coli* in genetic screens for mutations that increased the cellular mutation rate. Defects in *mut* genes result in an increased rate of base substitution and indel mutations (~1000-fold), as well as increased genetic recombination between divergent DNA sequences and gene amplifications. Mutant homologs of *mut* genes in mammals also have defects in cell-mediated death and immune-system functions. In humans, the high frequency of indel mutations seen in tumors obtained from a subset of patients suffering from inherited forms of nonpolyposis colorectal cancer (2–6% of all colon cancers), was a strong hint that these individuals suffered from defects in MMR. This characteristic resulted in the identification of mutations in at least four MMR genes that are linked to HNPCC. Loss of MMR activity has also been linked to resistance to chemotherapeutic agents (Figure 1).

Mammals contain multiple homologs of the *E. coli* *mut* genes. MutS homologs (MSH family), of which there are five members (MSH2–MSH6), act as heterodimers (Figure 2). MutS homolog proteins initiate the MMR pathway by recognizing mismatches. The primary complexes are MSH2–MSH6 (MutS α) and MSH2–MSH3 (MutS β). These complexes have

partially overlapping roles in recognizing mismatch substrates. MutS α is primarily involved in repairing base–base mismatches and small indel mutations. MutS β acts primarily to repair indels that are up to 17 nucleotides in length. MSH4 and MSH5 also form a heterodimeric complex that has no apparent role in MMR but acts to promote crossing over in meiosis. The lower eukaryote baker's yeast contains an MSH1 protein involved in mitochondrial genome stability; however, no mammalian homolog of MSH1 has been identified. Similarly, there are multiple MutL homologs (MLH family), MLH1, MLH3, PMS1, and PMS2, that function as heterodimers. The function of MutL homologs is to bridge mismatch recognition with the downstream repair steps of MMR. MLH1–PMS2 (MutL α) and MLH1–MLH3 (MutL γ) also have partially overlapping roles in initiating downstream repair from MMR targets. MutL α is the predominant complex in repairing mismatches and indels while MutL γ participates in only a subset of indel repair and in promoting crossing over in meiosis. MLH1 and PMS1 also form a heterodimeric complex; however, the function of this complex in mammals is less clear. Lastly, an MLH2 homolog has been identified in baker's yeast that has been implicated in the repair of frameshift mutations; however, an equivalent factor has not been identified in mammals. The downstream components of the mammalian MMR pathway do not belong to the Mut homolog families and are not MMR specific.

A key breakthrough in understanding the mechanistic details of the MMR pathway came from the development of a reconstituted MMR system from purified *E. coli* components. The substrate for this assay was a hemi-methylated plasmid containing a single mismatch; *in vitro* repair resulted in excision of the mismatch on the unmethylated strand (see later). This achievement led to a detailed characterization of individual bacterial

MMR components, and has served as the basis for characterizing key mammalian MMR factors.

In *E. coli*, MMR is initiated by a MutS homodimer binding to a DNA mismatch (Figure 2). Interactions between MutS, MutL, and mismatch DNA result in the removal of the mismatch through an excision mechanism. Excision is initiated by activation of the MutH endonuclease in steps that require MutS binding to mismatch DNA, MutL interaction with the MutS-mismatch complex, and ATP. MutH, a single-strand DNA cleaving enzyme that acts at unmethylated GATC sites, plays a critical role in a strand-discrimination mechanism that removes the mismatch on the newly replicated strand. Strand discrimination is accomplished by a MutH cleavage activity that is inhibited by Dam, a protein that specifically methylates adenine residues at GATC sites. Methylation of newly replicated DNA by Dam occurs within a short period after replication fork passage. This postreplication function of Dam establishes a strand-discrimination signal because MutH will not cleave methylated GATC sites but will cleave the unmethylated strand of hemi-methylated GATC sites. Thus, DNA mismatches that are recognized shortly after DNA replication fork passage are directed for removal of the newly replicated strand

due to MutH-directed cleavage of hemi-methylated GATC sites. MutH incision at hemi-methylated GATC sites can occur up to several thousand base pairs from the mismatch, with repair efficiency decreasing with distance.

MutH incision creates an entry site for UvrD, a helicase that can unwind duplex DNA beginning at a nick site with the aid of single-stranded DNA-binding protein (SSB). The MutS–MutL mismatch complex provides signals to load UvrD and unwind DNA toward the mismatch. The unwound single-stranded DNA containing the nicked end is acted upon by at least four exonucleases (ExoI, ExoVII, ExoX, and RecJ). These exonucleases display different polarities (5'–3' or 3'–5') for excision. Which nuclease acts depends on the orientation of the mismatch relative to which MutH cleavage site is chosen. Thus, the MMR system is capable of bidirectional repair (5'– or 3'–directed excision) and is able to sense the location of the mismatch to direct appropriate excision. The resulting gap created by excision is filled in by DNA polymerase III with the help of the replication-processivity factor β -clamp. DNA ligase closes the nick to complete repair (Figure 3).

Mammalian MMR shares aspects of the *E. coli* MMR mechanism with some important differences. Like in the *E. coli* system, the development of a cell-free system to study MMR has been critical in terms of identifying most of the key components. The main caveat, discussed here, is the fact that the cell-free system has not been able to address how strand discrimination is set up, other than showing that a preexisting nick on a mismatch plasmid substrate is sufficient to direct strand-specific repair.

As described earlier, mammalian MSH and MLH factors act as heterodimers to carry out functions analogous to those observed for the *E. coli* proteins. However, there are at least three mechanistic differences between the bacterial and mammalian MMR pathways:

1. A methylation system that distinguishes the template and newly replicated DNA strands does not appear to function in mammals and bonafide MutH homologs appears to be missing in eukaryotes and in most bacteria. Thus, mammalian MMR uses a different mechanism for strand discrimination. Models that outline how the mammalian MMR

Figure 1 Mutations seen in mismatch repair (MMR)-defective strains. Misincorporation mutations arise from DNA polymerase errors that create non-Watson–Crick base pairs. DNA slippage mutations commonly occur on repetitive DNA elements by DNA strands reannealing out of register. This creates an insertion (+) if the loop is on the newly replicated strand or a deletion (–) if on the template strand.

Figure 2 MMR components. (a) Mammalian mismatch repair. M = MLH1, P = PMS2, 2 = MSH2, 3 = MSH3, 6 = MSH6. A base–base mismatch is shown by the triangle and an indel created by DNA slippage is indicated by a half circle. Additional factors in mammalian MMR are shown. (b) Model replication fork from *E. coli*. A base–base mismatch is indicated by a diamond. Methylation by Dam is indicated by –CH₃.

Figure 3 Basic steps in MMR. (a) DNA mismatch is created by a DNA replication error. (b) Excision of the mismatch on the newly replicated strand creates a gap. (c) Resynthesis of the gap completes repair.

pathway distinguishes template from daughter strands have been proposed and will be discussed later.

2. A helicase activity analogous to UvrD does not appear to be required in cell-free mammalian MMR reactions.
3. Exonucleolytic activities that excise the newly replicated strand appear to work differently in mammalian MMR. So far, only a single exonuclease, EXO1, has been identified, and this protein is a 5' to 3' exonuclease that acts primarily on double-stranded DNA. The fact that EXO1 can act on double-stranded DNA may preclude the need for a helicase activity.

Mismatch Search and Recognition

MutS, the Mismatch Recognition Complex

Crystallographic analysis revealed that the MutS homodimer binds to mismatch DNA in an asymmetric fashion. In the absence of DNA, MutS contains disordered DNA-binding domains. Upon mismatch binding, these domains undergo extensive local folding to form more ordered structures. Each MutS subunit contains two DNA-binding domains; however, only one domain of one subunit directly interacts with a mismatched base while a DNA-binding domain on the other subunit makes nonspecific interactions to stabilize the DNA backbone. The overall structure of MutS resembles a clamp that encircles the DNA backbone. Studies on the crystal structures of the human MutS α complex have shown similarities with bacterial MutS in terms of domain organization and DNA interactions. In *E. coli* MutS, mismatch recognition is coordinated by two amino acids, phenylalanine 36 and glutamic acid 38. In mammals, MSH6, but not MSH2 or MSH3, contains these two key residues and is the subunit responsible for direct interactions with the mismatch. In both MutS and MSH6, the mismatch base stacks with the phenylalanine side chain and hydrogen bonds with the glutamic acid side chain. Moreover, the DNA bound to MutS in the crystal structure is in a bent state that is facilitated by these interactions and with nonspecific interactions between the other DNA-binding domain and the DNA backbone. Recent atomic force microscopy studies have suggested that MutS undergoes a conformational change after binding, which results in the formation of unbent DNA containing the mismatch. This type of manipulation may allow MutS to sample DNA for mismatches in a manner that increases target-recognition specificity.

MSH complexes must identify rare misincorporation errors among a vast excess of undamaged DNA. Biochemical and single-molecule studies have shown that MSH complexes can slide along DNA by facilitated one-dimensional diffusion; such a mechanism is likely to promote efficient identification of targets because the search is confined to scanning along DNA rather than requiring random collisions within the three-dimensional space of the nucleus. MSH complexes have also been shown to interact with components of the DNA replication machinery. This feature, coupled with their ability to diffuse along DNA, suggests that MSH complexes have immediate access to DNA polymerase-mediated misincorporation errors.

ATP binding and hydrolysis by the MSH proteins appear critical for coordinating mismatch recognition with the commitment to undergo excision repair. The MSH proteins are members of the ABC transporter adenosine triphosphatase (ATPase) family and they weakly hydrolyze adenosine triphosphate (ATP). Nucleotide binding results in conformational changes in MSH proteins. The nucleotide-binding sites of MSH proteins are found at their dimerization interface. MSH2 and MSH6 in MutS α show different affinities for adenine nucleotides. MSH6 has a higher affinity for ATP whereas MSH2 has a higher affinity for ADP. Nucleotide-binding asymmetry is also seen in the *E. coli* MutS homodimer. Such asymmetries in ATP binding by MSH subunits are considered to be important to induce coordinated conformational changes in MSH-mismatch DNA complexes that signal downstream repair factors. For example, in the eukaryotic MutS α (MSH2–MSH6) complex, upon mismatch binding, MSH6 ATP hydrolysis is inhibited and ATP binding by MSH2 is favored. This ADP $\rightarrow$ ATP nucleotide exchange allows MutS α to enter a sliding-clamp diffusion mode. Implications for a MutS α sliding-clamp diffusion mechanism in searching out the unknown strand-discrimination signal is discussed later (Figure 4). ATP is also required for recruitment of MLH proteins to mismatch–MSH complexes to form a ternary complex for the transmission of the mismatch-recognition signal to the downstream repair factors.

MutL Bridges Mismatch Recognition and Excision

As outlined above, the MLH family of proteins plays critical molecular matchmaking roles by signaling MSH-dependent mismatch recognition to downstream repair factors. Crystallographic structures have been reported for individual N- and

Figure 4 Model for signaling downstream repair. The molecular switch model proposes that after mismatch recognition, MSH-MLH complexes act as molecular switches triggered by nucleotide exchange. This exchange allows the complexes to enter a sliding-clamp diffusion mode in search of the unknown strand-discrimination signal. From Acharya S, Foster PL, Brooks P, and Fishel R (2003) The coordinated functions of the *E. coli* MutS and MutL proteins in mismatch repair. *Molecular Cell* 12: 233–246.

C-terminal fragments of the *E. coli* MutL protein. This analysis, described earlier, has shown that the MLH complexes undergo conformational changes that involve primarily the N-terminal domains. The existing structures lack connecting linker arms between the N- and C-terminal domains. Currently, only the N-terminal domains of the yeast and human PMS2 subunits (named PMS1 in yeast) have been solved.

The N-terminal domain of MutL family proteins contains an ATP-binding site that belongs to the GHKL family of ATPases. This domain in *E. coli* MutL dimerizes in the presence of a nonhydrolyzable ATP analog, AMP-PNP. ATP binding by GHKL family members induces large conformational changes in the proteins and such changes occur in the ATP-bound MutL proteins as well. The less-conserved C-terminal domain of MutL family proteins contains a region important for dimerization that does not appear to be modulated by nucleotide or other cofactors. The unstructured linker arms of MutL α become more ordered upon nucleotide binding and appear to promote interactions between the N-terminal domains of the two subunits.

Like the MSH family proteins, ATP hydrolytic activities appear different among the mammalian MLH subunits and are likely to be functionally relevant for coordinating interactions with downstream repair factors. MLH1 hydrolyzes ATP more proficiently than PMS2. In the absence of nucleotide, the overall structure of full-length MutL α is predicted to be a V-shaped molecule connected at the C-termini that undergoes conformational changes in the linker arms upon nucleotide binding to bring the N-termini together and form a ring-like structure. As previously mentioned, ATP has an apparent role in modulating the interactions of various components of the MMR pathway. MutS α bound to a mismatch is capable of interacting with MutL α in the presence of ATP to form a ternary complex. In the absence of a mismatch or ATP, MutS α and MutL α do not interact.

ATP-dependent dimerization of *E. coli* MutL is also a prerequisite for interactions with MutH and UvrD helicase.

What is the significance of the ATP-dependent conformational changes in MLH proteins? The ring-like structural topology of the MLH heterodimer in the presence of ATP suggests that DNA can thread through the central pore of the complex; such a structure could facilitate or regulate the sliding-clamp activities of the MSH complex (Figure 4). Consistent with this idea, biochemical analysis of MLH proteins has shown that they can bind to DNA; however, these proteins do not show an increased affinity for mismatched DNA. DNA binding by MLH proteins appears to be through nonspecific electrostatic contacts to the DNA backbone; such binding can be seen on both single-stranded and double-stranded DNA. There is also evidence for cooperative binding and polymerization along the DNA duplex.

It is unclear what role MLH DNA binding has in bridging mismatch recognition to downstream repair events. This activity, however, may be related to MutL α displaying a latent DNA endonuclease activity that is restricted to DNA near the mismatch site. This activity is essential for MMR and likely acts at the excision step of the process (see later). The endonuclease activity of MutL α resides in the PMS2 subunit and requires both ATP and heavy metal binding. Such an activity was not identified in MutL proteins from bacterial species that contain MutH and use the methylation-dependent strand-discrimination mechanism. Intriguingly, this observation hints at the possibility that the endonuclease activity of MutL α has replaced the requirement for MutH in higher organisms, though this is yet to be proven.

Downstream Steps in MMR

Downstream steps in MMR include strand discrimination, excision, resynthesis, and ligation. The factors that act in these steps do not appear to be MMR specific. They include (1) exonuclease 1 (EXO1), a factor required in multiple DNA repair pathways that acts in excision; (2) proliferating cell nuclear antigen (PCNA), the replication-processivity clamp required at multiple stages of MMR; the replication clamp loader (RFC) necessary for directing 3'-directed excision and proper loading of PCNA to initiate DNA synthesis; (3) replication protein A (RPA), an SSB that plays an important role in stimulating strand excision; (4) high mobility group protein B1 (HMGB1), a nonhistone chromatin associated protein likely having redundant functions with RPA; (5) DNA pol δ , a highly accurate polymerase used during resynthesis that fills in the gap created by excision; and (6) DNA ligase I, which seals the nick leftover after resynthesis to form an unbroken strand and complete repair. Coordination between each of these factors and each step of the MMR pathway is critical for efficient repair; the little that is known about how this is accomplished is indicated below. Mechanisms for strand discrimination, which are still being worked out, are discussed at the end of this section.

Excision

In reconstituted mammalian MMR involving a nicked mismatch substrate (typically a G–T mismatch), mismatch-dependent excision can be observed in the 5' to 3' or 3' to 5' direction, depending on the position of the strand nick in the DNA substrate relative to the mismatch. MutS α , RPA, and

the 5' to 3' double-stranded exonuclease EXO1 are sufficient for 5' to 3' excision from a nick to a mismatch; however, MutL α enhances mismatch dependence of this reaction by suppressing excision on homoduplex DNA by EXO1. Recent *in vitro* studies suggest that the addition of PCNA and RFC to a 3'-directed mismatch substrate is sufficient to promote 3' to 5' excision repair and to suppress inappropriate 5' to 3' excision. These observations raise the question of how EXO1, a 5' to 3' exonuclease, can support both 5'- and 3'-directed MMR. The finding that MutL α has a latent endonuclease activity that appears to be restricted to regions surrounding the mismatch provides an elegant solution; the endonuclease cleavages generated by MutL α are considered to provide an entry site for the 5' to 3' EXO1 exonuclease to act in bidirectional MMR.

Resynthesis

During reconstituted mammalian MMR, single-strand gaps are created during excision steps; these gaps can be as large as 1 kb in length and must be filled in by DNA polymerase and sealed by DNA ligase I to complete repair. The gaps created by excision span from a nick site introduced into a plasmid substrate (in lieu of a strand-specific repair signal) to roughly 150 base pairs beyond the mismatch site. The signaling mechanisms involved in coordinating excision and resynthesis steps are currently being worked out. Many of the MMR factors that act in early steps in MMR (MutS α , MutL α , RPA, PCNA, and RFC) have been implicated in both suppressing and terminating EXO1-mediated excision. The DNA synthesis steps in the reconstituted system are initiated by recruitment of DNA pol δ by PCNA that has been loaded by RFC.

Strand Discrimination: The Holy Grail in the MMR Field

Unlike many DNA repair events, where a lesion can provide localized information to direct repair, MMR uses information provided by the DNA replication machinery to remove the mismatch on the newly replicated strand. Perhaps the most interesting question remaining in the mammalian MMR field is how strand discrimination occurs. The nature of the strand-discrimination signal is unclear but genetic and biochemical evidence, obtained primarily from yeast and bacteria, suggest that it involves the identification of nicks on the newly replicated daughter strand (Figure 5).

The replication-processivity clamp PCNA interacts with many proteins, especially those involved in DNA repair, and this list includes the MutS α , MutS β , MutL α , and EXO1 MMR factors. In one model, PCNA provides a link between MMR and replication to allow mismatches to be identified immediately after formation by concentrating MMR factors at the replication fork. Like the hemi-methylation status of GATC sites in *E. coli*, nicks generated during replication are transient in nature. The identification of these nicks by MMR could, thus, be used as a strand-discrimination signal. PCNA is known to increase mismatch specificity of MutS α to activate EXO1 during excision and is required to initiate resynthesis by DNA polymerase. Furthermore, PCNA is always loaded onto junctions of single- and double-stranded DNA by RFC in a specific orientation. Thus, PCNA by virtue of its orientation upon loading could relay strand information through interactions with MutS α or MutL α . After MutS α or MutL α is oriented onto DNA, they could search out nearby strand discontinuities created during replication. There is also the possibility that a PCNA-independent mechanism orients MutS α or MutL α .

Figure 5 How might strand discrimination be accomplished during mismatch repair? Shown is a model of a replication fork with mismatches indicated by triangles. After mismatches are recognized, repair is directed to the daughter strand. Orientation of MutS α (MSH2-MSH6) or MutL α (MLH1-PMS2) to initiate excision of the newly replicated strand may be facilitated by interactions with proliferating cell nuclear antigen (PCNA). The nature of the strand-discrimination signal is unclear but is likely a nick created during replication. The lagging strand (bottom strand) contains unprocessed Okazaki fragments that provide nicks. The leading strand (top strand) would only generate nicks if the replication fork was restarted. Alternatively, it is possible that the DNA end at the elongating replication fork may serve to discriminate strands. MutL α could also be directed to cleave the correct strand to promote excision in each case.

Depending on the orientation of the strand discontinuity to the mismatch, excision can be directly started by the 5' to 3' exonucleases activity of EXO1 or, to allow 3'-directed repair by EXO1, would require a new strand break to be created on the opposite side of the mismatch through MutL α endonucleolytic cleavage. This model is supported by *in vitro* data showing that MutL α is dispensable on a substrate with a nick 5' to a mismatch, but is absolutely required for a substrate with a nick 3' to a mismatch. In order for the MMR system to utilize this mechanism, it would require relatively frequent strand discontinuities to be created during replication. Such discontinuities occur during lagging-strand synthesis where the average Okazaki fragment size is a few hundred base pairs. The fact that MMR appears more efficient on the lagging strand may reflect the high frequency of nicks that are accessible to MMR factors on this strand. There is little evidence for the presence of nicks on the leading strand at a density (every few kb) that would be utilized by MMR. However, several studies have suggested that leading-strand synthesis may not be as continuous as had been thought. One possibility is that like lagging-strand synthesis, replication is regularly restarted on the leading strand, thus creating strand discontinuities that can serve as a strand-discrimination signal. There is also the possibility that other undiscovered factors or signals play a role in this process.

Another point of contention in the field is how identification of the newly replicated strand is coordinated with mismatch recognition and downstream signaling. Recent evidence in bacterial and mammalian MMR systems suggests that MSH proteins form a sliding clamp with MLH proteins (Figure 4). Experiments in *E. coli* suggest that after mismatch recognition, MutS and MutL track along the helical contour to activate MutH to cleave the nearest hemi-methylated GATC site. These studies support a model in mammalian cells proposed by Rick Fishel and colleagues in which, following mismatch recognition, MSH-MLH complexes act as molecular switches that are triggered by nucleotide exchange to enter a sliding-clamp diffusion mode. In this model, MSH-MLH complexes then locate presently unknown strand-discrimination signals and guide excision steps that result in mismatch removal. An implication of this model is that multiple binding and release events can take place at the mismatch that may lead to polymer formation and communication between the two sites. The fact that MutL proteins can form polymers on DNA provides support for this idea. Excision needs to take place in the correct direction for competent repair to occur. Therefore, communication between the mismatch and the strand-discrimination signal is likely to be important because of the bidirectional nature of MMR.

Summary

The MMR system monitors the genome during DNA replication to ensure that mistakes made by DNA polymerases are corrected. A large group of repair factors acts in a coordinated

fashion to ensure accurate and timely repair. Some details of the repair process, such as how strand discrimination occurs to specifically remove errors on the newly replicated strand, are still unclear; however, the development of an *in vitro* mammalian MMR system from purified components, coupled with cell biological analysis of MMR factors, has provided a basic understanding of how MMR leads to mutation avoidance and how defects in this process can create a mutational load that can cause disease. The fact that mutations in many of the key recognition factors in MMR have been implicated in tumorigenesis illustrates the importance of MMR in maintaining mammalian genome stability.

DNA Modification, Restriction Endonucleases: Type I Enzymes

D T F Dryden and G A Roberts, University of Edinburgh, Edinburgh, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Host specificity of DNA (*hsd*) In a host expressing a type I restriction/modification (R/M) system, DNA containing the specific target sequence becomes modified or restricted, depending upon the methylation status of the target sequence.

Modification The process accompanying restriction by which host DNA is maintained in a state of sequence-specific methylation. Most restriction enzymes cannot cleave DNA, which has been modified by the methyltransferase partner. Type I restriction enzymes combine both restriction endonuclease and methyltransferase in one protein complex.

Restriction The process of hindering the propagation of bacteriophage through a bacterial culture. This process requires cleavage of the bacteriophage DNA by DNA-sequence-specific endonucleases commonly referred to as restriction enzymes.

Translocation Usually, the processive motion of an enzyme along DNA is described as translocation. However, for type I restriction enzymes, which remain bound to their initial target sequence, translocation refers to the pulling in of DNA toward the enzyme.

Biochemical Function

Type I restriction enzymes are large complexes with multiple enzymatic functions, and they possess the ability to switch between these functions depending upon the chemical nature of specific nucleotides within a target DNA sequence. A demonstrated function of type I enzymes in their natural hosts, eubacteria and archaea, is to protect the host from infection by foreign DNA from bacteriophages. This protection is achieved by two processes – modification of the host DNA by methylation at the N6 position of adenine nucleotides within the recognition sequence targeted by the enzyme and destruction of invading DNA, which typically lacks the appropriate modification of the target sequence. For a host specifying a type I restriction enzyme, typically far fewer than one in a thousand phage particles successfully infect the host. Therefore, the type I restriction enzymes are a very effective defense system despite the considerable resources devoted by the host cell to their synthesis. This protective function is termed ‘restriction’ and results in the destruction of the phage DNA once it has entered the host cell. Methylation of host DNA occurs during each round of DNA replication. The newly synthesized DNA strand lacks the appropriate methylation, the type I restriction enzyme recognizes this DNA as hemimethylated and adds the methyl group to the adenine in the target sequence in the newly synthesized strand. In this manner, the type I restriction enzyme recognizes three different states of methylation of its target sequence, unmodified, hemimethylated, and fully modified, and performs a different reaction on each form of DNA (Figure 1). *In vitro*, the efficiency or accuracy of the switching between activities varies depending upon the particular type I restriction enzyme. For example, EcoKI, the type I restriction enzyme in *E. coli* K12, and EcoR124I, a plasmid-encoded type I R/M system, are very precise, methylating only hemimethylated targets and cutting only unmodified ones. In contrast, EcoAI from *E. coli* 15T[−] methylates unmodified targets as effectively as hemimethylated targets; as a result, this activity competes with the restriction of unmodified DNA. These three enzymes are the best-characterized members of the type I restriction enzymes.

Genes and Protein Structure

It has been shown that three genes are required to specify a type I R/M system: *hsdS*, *hsdM*, and *hsdR*, where *hsd* refers to host specificity for DNA and *S*, *M*, and *R* stand for specificity, modification, and restriction, respectively. Typically, the *hsdR* gene is expressed from its own promoter and the *hsdM* and *hsdS* genes from a single promoter upstream of *hsdM*. The *hsdR* gene is typically close to *hsdM/hsdS*, although some genome sequences suggest that this is not always the case. Genome rearrangements also occur around the *hsd* locus and this is used to induce some interesting switching of the expression and target-sequence specificity of alternative type I R/M systems within a cell. Most studies have concentrated upon the type I R/M systems of *E. coli* and *Salmonella enterica*, and it has been found in these hosts that type I R/M systems can be divided into at least four families based upon the following criteria: DNA hybridization, antibody cross-reactivity, and genetic complementation of the *hsd* genes from different systems. These families are known as type IA, IB, IC, and ID. Structural and bioinformatics studies of the Hsd subunits have been used to understand the basis of these families. Within a family, amino acid sequence identity of the three expressed polypeptides is very high except for two regions of HsdS involved in DNA target recognition. Amino acid sequence identity between polypeptides from different families is much lower and is usually confined to regions of HsdS involved in DNA target recognition, if the R/M systems being compared share at least part of the same DNA target sequence specificity, and to short motifs involved in catalysis.

The Sequence Specificity Subunit

HsdS, often referred to as the S subunit, is responsible for recognizing the characteristic bipartite, asymmetric DNA target sequence of type I restriction enzymes; for example, the target for EcoKI is 5′-AACNNNNNNGTGC-3′, where N is any base. S subunits have a mass of approximately 50 kDa and comprise five regions of primary structure (polypeptide sequence)

Figure 1 The operations performed by a typical type I restriction enzyme are illustrated using the EcoKI enzyme binding to its DNA target sequence AACNNNNNGTGC and determining the methylation status of the target. The sequence of operations is: target location, methylation recognition, switching between different activities, and performance of the selected action.

Figure 2 Diagrams of a typical S subunit of a type I restriction enzyme. The upper diagram shows the subunit as a linear representation from the N-terminus to the C-terminus. Regions of sequence conservation between different S subunits are shown hatched. Regions within the subunit with sequence conservation have the same sort of hatching. The conserved regions flank the TRDs responsible for DNA sequence recognition. Each TRD recognizes one part of the bipartite target sequence. The lower diagram depicts the folded arrangement of these regions making apparent the approximate twofold rotational symmetry axis of the S subunits.

(Figure 2). There are sequences (conserved regions) at the N-terminus, the central part of the polypeptide, and at the C-terminus that are highly conserved within a family of type I restriction enzymes and show some identity between families. Separating these three conserved regions are two longer sequences that display very limited sequence identity between different S subunits unless the different S subunits recognize the same DNA target sequence or one part of the same target sequence. These polypeptide sequences (variable regions) are associated with recognition of DNA target sequence and each region recognizes one part of the bipartite target sequence of the enzyme. These two variable regions each fold into a tertiary structure domain referred to as a target recognition domain (TRD). A weak sequence identity exists between the TRDs of the S subunits and the TRD of methyltransferases from type II R/M systems. This identity covers a region involved in DNA

sequence recognition. Indeed, extensive mutagenesis of a TRD from HsdS of EcoKI corroborated this similarity between TRDs from type I and type II R/M systems. The conserved polypeptide regions flanking the TRDs are structural components required to position the TRDs against the DNA target and to act as a scaffold for the binding of the M and R subunits. Some *hsdS* genes have been manipulated to exchange TRDs from different type I R/M systems. The resulting chimeric HsdS recognize new target DNA sequences. In addition, sequence similarity between conserved regions within an S subunit suggested an approximate twofold degree of symmetry in the subunit. A polypeptide comprising one TRD and part of the conserved regions formed a dimeric protein recognizing a twofold symmetrical DNA target. Within a family, the length of the central conserved region influences the number of nonspecific bases found in the DNA target sequence. Thus, naturally occurring variation in the structure of *hsdS* genes has led to the evolution of new target specificities. Kim and colleagues presented the first crystal structure of an S subunit from *Methanococcus jannaschii*. The essential features of the structure include two TRDs of almost identical topologies separated from one another by a coiled coil of long antiparallel α -helices. The interface between the two helical coils is made up of a plethora of hydrophobic residues. Thus, the coiled-coil region resembles a molecular ruler that facilitates recognition of the bipartite target sequences by appropriate orientation of the two TRDs. Moreover, the structure suggests that the bound DNA is subject to bending and exposure of the target adenine bases.

The Modification Subunit

Two M subunits bind to HsdS to form a core trimeric enzyme with the properties of sequence specificity, detection of DNA methylation (whether hemimethylated or unmethylated), binding of methylation cofactor S-adenosyl-methionine (SAM), and methyltransferase activity. These M subunits have an approximate molecular mass of 60 kDa. The central third of the polypeptide sequence contains a series of amino acid motifs that are found in SAM-dependent methyltransferases and are involved in binding of the cofactor, binding of the adenine base specified for methylation, and catalytic transfer of the methyl group from SAM to the N6 position of the adenine base. This region of the M subunit has been successfully modeled upon the catalytic domain of the methyltransferases of type II R/M systems. Mutations in the motifs found in this catalytic domain have deleterious effects on activity. Methylation by type I restriction enzymes almost certainly occurs via the same nucleotide flipping mechanism used by methyltransferases of type II R/M systems in which the base targeted for modification is displaced from the DNA double helix into a catalytic pocket in the SAM-binding catalytic domain. The N-terminal part of the M subunit of EcoKI appears to play a role in recognition of the methylation status of the DNA target sequence and mutations reduce the preference of EcoKI for methylating only hemimethylated DNA. The C-terminal region of M subunits appears to be important in interacting with the S subunit to form the core assembly. The polypeptide sequences of M subunits are almost identical within the same type I R/M family, but identity between families is mostly confined to the motifs in the catalytic domain.

The Restriction Subunit

The complete type I restriction enzyme is formed by adding two R subunits to the core trimer to form a complex with subunit stoichiometry $R_2M_2S_1$ and a mass of around 440 kDa, an enormous multifunctional molecular machine. As for HsdM, the R subunits show high sequence identity for members in the same family but lower identity, confined to a series of amino acid motifs, for comparisons between families. The complete restriction enzyme is still capable of methylating the DNA target sequence if it is hemimethylated and, if it is a type I R/M system of low preference such as EcoAI, of methylating unmethylated targets as well. However, unmethylated DNA target sequences primarily trigger the restriction reaction. The R subunits contain three main regions. An N-terminal domain contains an amino acid motif found in DNA endonucleases, particularly endonucleases from type II R/M systems. Mutagenesis experiments reveal that this domain is responsible for DNA cleavage by type I restriction enzymes. The central portion of the subunit contains a further set of amino acid motifs characteristic of the so-called DEAD-box helicases, enzymes that translocate or move DNA. These motifs form a multidomain structure that binds and hydrolyzes adenosine triphosphate (ATP) and couples this hydrolysis to the movement of DNA relative to the enzyme (DNA translocation). Mutation abolishes the ability to hydrolyze ATP and translocate DNA. In the absence of translocation, the enzyme cannot cut DNA and restriction activity is lost even though the endonuclease domain is unaltered. The C-terminal region of HsdR appears to be required for interaction with the core trimer. Lapkouski and colleagues presented the first crystal structure of an R subunit from EcoR124I in complex with Mg^{2+} and ATP. The overall structure is composed of four globular domains in a square-planar arrangement. Each domain is separated from its near neighbor by a prominent groove. Analysis of the structure, in particular, the shape and electrostatic character of the grooves, together with biochemical data, has allowed the authors to propose a path taken by a bound DNA molecule during translocation.

Assembly and Control of the Type I Restriction Enzyme

The assembly of the complete type I restriction enzyme is a complex affair and many type I R/M systems can form proteins with different subunit stoichiometries. The main partially assembled form of type I restriction enzymes is a trimer M_2S_1 , which forms a fully functional modification methyltransferase recognizing the same DNA target as the complete enzyme. Taylor and colleagues have recently presented small-angle neutron scattering experiments on an engineered version of the type I DNA methyltransferase of EcoR124I to obtain a low-resolution structural model. Other partially assembled forms and even individual subunits have been isolated and can display some limited activities such as sequence specificity, cofactor binding, and, for the $R_1M_2S_1$ form of EcoR124I, DNA methylation and ATP hydrolysis-driven DNA translocation. Intracellular concentrations of the Hsd subunits vary with host conditions and it has been suggested that concentration-dependent assembly may play a role in the establishment of type I R/M systems in new hosts. It has also been shown that when the host cell acquires unmodified target sequences after

suffering DNA damage, the restriction activity of type IA and IB R/M systems is controlled by proteolytic digestion of HsdR. This control process prevents the type I restriction enzyme from attacking the unmodified target sequences in the damaged host chromosome.

The Restriction Reaction

DNA Binding and Recognition of Unmodified DNA

The type I restriction enzymes display a strong preference, in the presence of their cofactors, for binding to their DNA target sequence rather than to other DNA sequences. Although sequence specificity resides within HsdS, the presence of HsdM appears to be essential for strong binding to DNA. Once bound, the HsdM plus SAM detect the presence of adenine methylation on each strand of the DNA target using the base-flipping mechanism. If the adenine is already methylated, then it will not be able to fit properly into the catalytic site as the methyl group will clash with the methyl group of SAM. This steric hindrance appears to change the conformation of the enzyme to allow the methylation reaction to proceed upon hemimethylated DNA or to dissociate from fully modified DNA. However, if both adenines are unmethylated, they can be accommodated within the HsdM along with SAM. The absence of steric hindrance for both target adenines appears to be the trigger for the highly complicated restriction reaction.

Upon recognition of an unmodified target site, the restriction enzyme becomes strongly attached to the DNA target site and does not appear to dissociate from the DNA after carrying out the restriction reaction. Strictly speaking, this lack of enzymatic turnover in the complete process means that type I restriction enzymes are not enzymes. If the DNA molecule contains more than one target site, the type I restriction enzymes bound at each site can stick to each other to form a large complex. This additional DNA-dependent dimerization of the enzyme arises from diffusional motion of the DNA molecule bringing the bound enzymes into contact and does not depend upon enzyme activity. The functional role, if any, of this dimerization is not known as it is not necessary for restriction.

ATP Hydrolysis

Unmodified DNA target sequences trigger the hydrolysis of large amounts of ATP. The ATPase activity continues throughout the DNA translocation and cleavage process and continues even after DNA cleavage. The purpose of this continuing ATP hydrolysis observed *in vitro* is not known but may represent continuing DNA translocation on the cleaved DNA substrate.

DNA Translocation

The enzyme remains bound to the target sequence and commences pulling DNA on either side of the target sequence toward itself. As it is still attached at the target sequence, loops of DNA appear to be extruded from the enzyme (Figure 3). This process requires ATP hydrolysis and generates extensive supercoiling in the DNA. The reeling in of DNA occurs at approximately 500 base pairs (bp) per second and has been shown to occur over huge distances up to approximately 50 000 bp.

Figure 3 The sequence of events occurring after the type I restriction enzyme (oval) has bound and recognized an unmodified DNA target sequence (black box) on a DNA molecule (thin line). ATP hydrolysis drives the translocation of DNA, reeling the DNA in toward the enzyme with, as a consequence, the extrusion of loops of DNA. Eventually, translocation is blocked by, in this example, collision with a second translocating type I restriction enzyme, whereupon cleavage occurs at the collision point. After cleavage *in vitro*, the enzymes remain bound to their target sequence.

Single-molecule experiments performed by Seidel and colleagues to analyze the DNA translocation of EcoRI 24I demonstrate that the two R subunits work independently. The same study showed that, in this case, translocation was limited to ~4300 bp per binding event, which is much shorter than reported for other type I enzymes. The apparent discrepancy may be due to instability of the EcoRI 24I assembly, leading to the dissociation of the R subunit from the remainder of the enzyme.

Stalling of the movement appears to occur when the translocating enzyme collides with a blockage on the DNA. This blockage can be another translocating type I restriction enzyme if there are two or more target sequences on a particular DNA molecule, stalling on a circular DNA molecule containing only one target sequence or collision with a complex DNA structure such as a fixed Holliday junction.

Cleavage of DNA

Translocation blockage appears to be the signal for cutting of the DNA strands at the stalling location. Cutting does not occur at the original target sequence. As translocation rates of individual type I restriction enzymes on a DNA molecule may vary depending upon the particular enzyme species and upon the sequence being translocated, individual enzymes will stall or collide with each other at different locations on the DNA. Hence, in a solution containing many DNA molecules, translocation blockage and DNA cleavage occur at a range of locations. For a DNA molecule containing two or more target sequences for the same type I restriction enzyme, cleavage occurs approximately halfway between the original DNA target sequences. For a DNA molecule containing target sequences for different type I restriction enzymes, the approximate location of cleavage depends on the relative translocation speeds of the different enzymes. Thus, DNA cleavage by type I restriction enzymes does not produce DNA fragments of defined length and sequence but rather a broad range of fragment lengths. Circular DNA molecules containing one target sequence are also cleaved at an undefined distance from the target sequence. The presence of a nick in a DNA molecule appears to bias the cleavage event to be close to the nick.

Anti-Restriction

Despite their complexity, type I restriction enzymes are very effective barriers against horizontal gene transfer. However,

bacteriophages have developed a range of counter-measures to overcome this barrier. These anti-restriction strategies include selection against the presence of target sequences, modification of DNA bases, hydrolysis of the SAM cofactor, and the use of genes encoding specialized proteins that act as competitive inhibitors of DNA binding by type I restriction enzymes.

This last strategy is employed by bacteriophage T7, which produces gene 0.3 protein, also known as overcome classical restriction (Ocr), immediately upon infection of *E. coli*. Ocr binds very strongly to all characterized type I restriction enzymes, irrespective of their DNA target sequences, and prevents the enzyme from binding to DNA. The crystal structure of Ocr has been solved by Walkinshaw and colleagues to a resolution of 1.8 Å. The protein exists as a highly extended homodimer that mimics the size and shape of a bent B-form DNA duplex of ~24 bp in length. Furthermore, the protein is replete with acidic residues that mimic the negative charges of the phosphate backbone of the DNA molecule. Stephanou and colleagues have demonstrated that extensive neutralization of the acidic residues of Ocr by chemical modification, while leaving the overall protein fold largely unaffected, reduced the affinity of the molecule for the M₂S₁ methyltransferase (M.EcoKI) of EcoKI by as much as 800-fold. Electron microscopy analysis by Kennaway and colleagues of the M.EcoKI:Ocr complex, combined with modeling data indicate that Ocr is completely enveloped by M.EcoKI and fits perfectly into the DNA-binding site of type I restriction enzymes. In addition, the proposed model is entirely consistent with a large body of experimental data that has accumulated over some 40 years of research on EcoKI. Recently, McMahon and colleagues solved the crystal structure of the ArdA anti-restriction protein from the conjugative transposon Tn916. Like Ocr, the ArdA protein is a homodimer with an extended curved cylindrical structure. However, the ArdA protein is even more elongated than Ocr and mimics a ~42 bp stretch of B-form DNA – by far the longest DNA mimic yet described. Furthermore, the distribution of negative charge on the molecule shows an obvious mimicry with that of the DNA double helix.

The question of how DNA mimics, such as Ocr and ArdA, could have arisen through the process of natural selection is intriguing. Sequential acquisition of point mutations to generate codons corresponding to acidic residues seems a highly unlikely event. Nonetheless, once established, a mimic can spread efficiently throughout its biological niche. For example, ArdA is widespread in eubacteria on plasmids and transposons while Ocr-related proteins are common in bacteriophages related to the T7 phage. More research needs to be undertaken

to fully understand the evolutionary origins of these DNA mimics and their biological role in assisting horizontal gene transfer.

Glossary

AP site A nucleotide in DNA that has lost the nucleobase.

DNA damage Any change in the bases (Ade, Cyt, Gua, and Thy) or phosphodiester backbone structure that comprise canonical DNA.

DNA repair Any enzymatic process that participates in purging DNA of damaged elements and returns it to its canonical form.

Lesion A damaged nucleotide in DNA.

Reactive oxygen species A molecule that contains an oxygen atom with a highly reactive configuration of electrons.

Oxidants and Antioxidants

Oxygen-releasing photosynthesis and aerobic respiration have provided the basic machinery of life for almost 3 billion years and have driven the evolution of complex life forms. The reduction of oxygen to water, due to spin restrictions imposed on an O_2 molecule, proceeds in sequential steps involving three reactive oxygen species (ROS): superoxide anion radical, hydrogen peroxide, and hydroxyl radical:

Additionally, molecular oxygen in the 1A_g excitation state (singlet oxygen) is included in the category of ROS. Reactive nitrogen species, such as peroxynitrite $ONOO^-$ formed upon recombination of O_2^- with an important signaling molecule, NO, are often considered together with ROS due to their similar biological effects. In cells, ROS react with many molecules, with their average lifetime and distance of diffusion from the point of generation being inversely related to their reactivity. Free radicals, such as O_2^- and $HO\cdot$, trigger chain reactions of oxidation, allowing unpaired electrons to migrate over longer distances. Unsaturated fatty-acid side chains are especially prone to reactions with free radicals; the resulting peroxy radicals propagate by a chain reaction. Given the ubiquitous presence of phospholipid membranes in cells, lipid peroxidation also plays an important role in the toxicity associated with ROS.

The primary source of ROS in eukaryotes is the mitochondrial respiratory chain. Approximately 0.1% (under phosphorylating respiration) to 2% (under resting respiration) of consumed oxygen is converted to ROS, primarily through auto-oxidation of the semiquinone forms of ubiquinone and flavin mononucleotides in complex I and complex III. In plants, photosystem I is also a major producer of ROS.

Other cellular redox systems are also capable of producing ROS. Important nonmitochondrial endogenous sources of ROS are reactions catalyzed by cytochromes P450, NADPH oxidase, xanthine oxidase, etc. In mammals, immunoglobulins generate ROS through oxidation of water by singlet oxygen.

The major environmental source of ROS is ionizing radiation. Radiolysis of water releases hydroxyl radicals and other

reactive entities, such as solvated electrons, $H\cdot$ and $\cdot O^-$ radicals. Other sources of ROS include ultrasound, photosensitizing dyes (methylene blue and rose bengal), transition metal ions, ozone, a variety of salts (e.g., $KBrO_3$), and certain drugs.

Hydroxyl radicals and singlet oxygen are the most reactive forms of ROS and, consequently, the most damaging to biomolecules. Hydroxyl radicals are generated from superoxide and H_2O_2 by Fenton chemistry when Fe^{2+} or other low-valence transition metal ions are present; such ions bind to DNA and these reactions play an important role in DNA damage:

In living organisms, various mechanisms have evolved to minimize the effects of oxidative damage, including deactivation of ROS by superoxide dismutases, catalases, and peroxidases. Superoxide dismutases (SODs) are ubiquitous metal-dependent enzymes that contain Cu/Zn, Mn, Fe, or Ni ions. All forms of SOD catalyze the dismutation of superoxide radicals into hydrogen peroxide and oxygen:

At the next stage of oxygen reduction, hydrogen peroxide is converted to water and oxygen by catalase:

or peroxidase:

Almost any low-molecular-weight substance that contains a reducing moiety can react with ROS. Such nonenzymatic radical scavengers are present in significant quantities in cells or concentrated at ROS target sites. These antioxidants include lipophilic substances (α -tocopherol and β -carotene) and hydrophilic molecules (ascorbic acid, uric acid, glucose, and glutathione) that prevent transition metals from producing hydroxyl radicals. The low concentrations of free Fe^{2+} in mammalian cells are due to the presence of intra- and extracellular proteins that bind and sequester iron (ferritin and transferrin) or oxidize it (ceruloplasmin).

DNA Damage

DNA is an important target of oxidative damage. Both the sugar–phosphodiester backbone and the bases are subject to attack by ROS, producing single- and double-strand breaks, intra- and interstrand cross-links, abasic (AP) sites, cyclonucleotides, and a variety of modified bases. Lipid-derived radicals induced by ROS also damage DNA. All DNA bases are subject to direct oxidation; some of the principal lesions detected in cellular DNA are shown in **Figure 1**. A characteristic feature of ROS-mediated radiation damage to DNA is production of clustered lesions, which are separated by less than 20 base pairs and are easily converted to double-strand breaks.

8-Oxoguanine

One of the most prevalent and best-studied oxidized bases in DNA, 8-oxoguanine (8-oxoGua), is formed by oxidation of guanine at C8. Almost all endogenous and environmental sources of ROS can induce the appearance of 8-oxoGua. Of several different mechanisms of its formation, two are likely the most important in biological systems: one involves an attack by $\text{HO}^\bullet$ at C8 of Gua, another is initiated by singlet oxygen addition at C4–C8.

Several methods of detection (electrochemical, mass spectrometry, ^{32}P -postlabeling, immunoassay, and comet assay) and efficient synthetic protocols have been developed for this lesion, making it a widely used biomarker of oxidative DNA damage and the substrate of choice to study the repair of oxidative DNA damage. Under normal conditions, human

genomic DNA contains approximately one 8-oxoGua base per 10^6 Gua, and this level significantly increases in many pathologic conditions.

Like all purine nucleotides substituted at C8, 8-oxo-2'-deoxyguanosine can easily adopt the *syn* conformation. In the normal *anti* conformation, 8-oxoGua forms a Watson–Crick pair with Cyt, whereas in the *syn* conformation, it forms a Hoogsteen pair with Ade. This ability provides the basis for mutagenic properties of 8-oxoGua. Nevertheless, 8-oxoGua has almost no impact on the three-dimensional structure of DNA; both types of 8-oxoGua-containing pairs are easily accommodated in regular B-DNA. This base can also be easily oxidized further, forming several possible products (e.g., guanidinohydantoin), each having its own biological consequences.

Formamidopyrimidines and Oxidized Adenine Lesions

Although Gua is the most easily oxidized purine, Ade can be converted to 8-oxoadenine through the same hydroxyl radical chemistry. However, Ade is more prone to form another oxidative product, 2-hydroxyadenine. Another important class of purine oxidation products, formamidopyrimidines, is formed when 8-hydroxyguanylyl or 8-hydroxyadenylyl radicals are reduced rather than oxidized to 8-oxopurines. The yields of 8-oxopurines and formamidopyrimidines are similar, making the latter biologically important as well. Generally, physicochemical properties of formamidopyrimidines, their base-pairing capabilities, and their interactions with DNA polymerases and DNA repair proteins are similar to their counterpart 8-oxopurines.

Figure 1 Examples of major oxidative lesions in DNA.

Oxidized Pyrimidines

Oxidation of pyrimidines initiated by HO[•] leads to the formation of three primary radicals (at C6, C5, and exocyclic C5 in the case of Thy) and a wide spectrum of products of their further conversion. Pyrimidine oxidation may be accompanied by deamination (as in 5-hydroxyuracil, a derivative of Cyt), ring contraction (as in 5-hydroxy-5-methylhydantoin), opening, or fragmentation. Some damaged pyrimidines that are technically not oxidized, such as 5,6-dihydropyrimidines, are also included in this class because they are produced as a part of spectrum of true oxidized pyrimidines during irradiation. Many oxidized pyrimidines lose their planarity, making them much more distorting for DNA than oxidized purines discussed earlier.

Products of Deoxyribose Oxidation

DNA oxidation involving the deoxyribose moiety often leads to base loss and DNA strand cleavage with a variety of abasic sites produced and a variety of ends generated at the site of the break. However, two classes of oxidative lesions retain the base and the integrity of the DNA strand: 8,5'-cyclopurines and α -anomers of nucleotides. Oxidation of deoxyribose forms a basis of action of important anticancer drugs, bleomycin and neocarzinostatin.

Biological Effects

Cytotoxicity and Mutagenesis

The major cytotoxic effects of ROS represent responses to DNA double-strand breaks and lesions that block replication. Certain oxidized bases are mutagenic, for example, 8-oxoGua accommodates a miscoding base (Ade) during DNA synthesis. The proofreading activity of DNA polymerases fails to remove deoxyadenosine monophosphate (dAMP) when it is incorporated opposite 8-oxoGua. Thus, mutations at 8-oxoGua are predominantly G→T transversions. DNA polymerases differ significantly with respect to nucleotide insertion opposite 8-oxoGua. Replicative polymerases (e.g., eukaryotic DNA polymerases α and δ and bacterial DNA polymerase III) are strongly blocked by 8-oxoGua and preferentially insert dAMP opposite this damaged base, while polymerases involved in DNA repair (such as eukaryotic DNA polymerase β and bacterial DNA polymerase I) mainly incorporate dCMP. DNA polymerases responsible for lesion bypass (e.g., eukaryotic DNA polymerases ζ , η , and κ , and bacterial DNA polymerases II, IV, and V) can insert both dAMP and dCMP opposite 8-oxoGua. On the other hand, oxidized pyrimidines, due to their nonplanar structure, often strongly block DNA polymerases.

Deoxynucleotide triphosphates are also subject to damage by ROS, promoting base misincorporation, which may lead to mutational events. In addition to their harmful consequences associated with replication, oxidative lesions in DNA may promote so-called transcriptional mutagenesis by instructing RNA polymerases to misincorporate dNMPs, which then may lead to amino-acid substitution or early termination of translation. The presence of oxidative lesions in DNA is known to interfere with binding of some regulatory proteins and with action of DNA-processing enzymes, such as helicases or topoisomerases.

Carcinogenesis

Oxidative stress is an important factor in tumor initiation and promotion. It is clear that somatic mutations play a central role in carcinogenesis and oxidative DNA damage has been implicated as an initiating event in this process. Its importance can be appreciated by noting that the amount of oxidized bases in DNA is significantly higher than the amount of DNA adducts formed by well-established chemical carcinogens. The role of ROS in tumor development may also be attributed, in part, to their mitogenic properties and their ability to damage cellular proteins and membranes.

8-oxoGua and thymine glycol are frequently used as biomarkers for oxidative DNA damage. DNA in tumors usually contains increased amounts of oxidized bases. As solid tumors are often hypoxic and display lower levels of general oxidative damage, this increase in DNA damage appears to be a cause rather than a consequence of neoplastic transformation. For tumor development to occur, a series of mutations are generally required to inactivate tumor suppressor genes and/or alter the status of protooncogenes. The presence of G→T transversions, characteristic of 8-oxoGua, suggests that oxidative damage may have been involved in these instances. This signature transversion is found in mutated *TP53* and *RAS* genes in many human cancers and experimental systems.

Aging and Age-Related Diseases

In 1956, D. Harman proposed a free-radical theory of aging. Oxidative DNA damage increases with age and the correlations between aging and DNA oxidation are reflected in increasing levels of 8-oxoGua and thymine glycol. The relationship between an organism's life span and its ability to repair oxidatively damaged DNA has also been reported.

High levels of 8-oxoGua are present in several age-related noncancer pathologies, such as Parkinson's disease. Although the frequency of mutations increases with age, there are no documented cases of somatic mutations in the nuclear genome that are directly involved in age-related changes or age-related diseases, with the exception of spontaneous cancers and trinucleotide repeat pathologies. Oxidation of DNA increases its immunogenicity, potentially contributing to development of autoimmune diseases. Mitochondrial DNA (mtDNA), rather than nuclear DNA, has been proposed as a principal site of age-related damage accumulation. Direct estimates of oxidative damage in mtDNA usually are much higher than those in nuclear DNA. A specific, age-related deletion in the mtDNA of postmitotic cells, as well as multiple rearrangements, has been documented.

Repair of Oxidative DNA Damage

General

DNA damage occurs to a significant degree despite the ubiquitous presence of ROS scavengers. However, several cellular repair mechanisms are available: direct reversal, base excision repair, nucleotide excision repair, mismatch repair, recombination repair, and nonhomologous end-joining. Double-strand breaks are generally repaired by recombination repair or nonhomologous end-joining; interstrand cross-links, by a

Figure 2 GO system in bacteria.

combination of nucleotide excision repair and recombination repair; and intrastrand cross-links and cyclonucleotides, by nucleotide excision repair. Most oxidative damage is dealt with by base excision repair. Here, damaged bases are excised by specific DNA glycosylases, creating an AP site, and an AP endonuclease then cleaves DNA 5' to this position. Deoxyribose phosphate lyase removes the sugar residue, creating a substrate for a DNA polymerase. After the polymerase fills the resulting gap, a DNA ligase restores the double-stranded DNA. Several variations of this essential scheme exist.

Despite the wide variety of oxidatively damaged bases found in DNA, only a few glycosylases are involved in their repair. These enzymes necessarily exhibit broad substrate specificity, with some acting primarily on oxidized pyrimidines and others on oxidized purines. In *Escherichia coli*, oxidative damage to pyrimidines is repaired by endonuclease III (Nth) and endonuclease VIII (Nei); structurally related enzymes perform similar functions in eukaryotes (NTHL1, NEIL1, NEIL2, and NEIL3 in humans). More than 20 types of oxidized bases are excised by these DNA glycosylases. Depending on the chemistry performed by the DNA glycosylases, modified nicks of different nature are generated in DNA and processed by different AP endonucleases and phosphatases to create a suitable end for the DNA polymerase.

GO System

8-oxoGua presents a special problem for DNA repair. Since either dAMP or dCMP can be incorporated opposite it, the repair system must convert both 8-oxoGua:Cyt and

8-oxoGua:Ade mispairs into a Gua:Cyt pair. At least two cycles of base excision repair are required to repair 8-oxoGua:Ade. First, Ade, the normal base, is excised, a process followed by insertion of dCMP opposite the lesion. The resulting 8-oxoGua:Cyt mispair is then repaired by excision of 8-oxoGua and subsequent insertion of dGMP.

In *E. coli*, a system of three enzymes – Fpg (MutM), MutT, and MutY (GO system) – counters the deleterious effects of 8-oxoGua (Figure 2). MutT, a nucleotide hydrolase, cleanses the cellular nucleotide pool of 8-oxodGTP. Fpg is an 8-oxoguanine-DNA glycosylase that excises 8-oxoGua from 8-oxoGua:Cyt, but not from 8-oxoGua:Ade. MutY protein is an adenine glycosylase specific for Ade:8-oxoGua and Ade:Gua pairs. If 8-oxoGua in DNA arises by spontaneous oxidation of Gua or by incorporation of 8-oxodGMP opposite Cyt, it is excised by Fpg. However, if Ade:8-oxoGua is present because of misincorporation of 8-oxodGMP opposite Ade, it becomes a substrate for MutY. If dAMP is inserted again by a DNA polymerase after excision by MutY, the cycle of MutY repair is repeated, whereas dCMP insertion converts the 8-oxoGua:Ade mispair to 8-oxoGua:Cyt, a substrate for Fpg. The GO system also operates in most eukaryotes; in humans, OGG1 protein is a functional analog of Fpg, MUTYH is a homolog of MutY, and NUDT1 is a homolog of MutT. Certain polymorphisms of OGG1 confer increased risk of lung cancer, and inactivating mutations of MUTYH cause colorectal cancer.

Glossary

Apurinic/aprimidinic (AP) site DNA lesion resulting from the loss of a base (i.e., abasic site). These sites can be mutagenic since they have lost their coding potential or cytotoxic since they are quickly incised resulting in DNA strand breaks.

C-subdomain One of the three subdomains found in all DNA polymerases. This subdomain includes three active site acidic residues that coordinate two metals (Mg^{2+}) that assist nucleotidyl transfer. It is also referred to as the palm subdomain in the polymerase nomenclature that utilizes the analogy to a right hand.

D-subdomain One of the three subdomains found in all DNA polymerases. This subdomain interacts with duplex DNA upstream of the primer terminus. It is also referred to as the thumb subdomain in the polymerase nomenclature that utilizes the analogy to a right hand.

DNA polymerase β A small eukaryotic DNA polymerase involved in short-gapped DNA repair synthesis. In addition to its polymerase activity, this polymerase contributes an accessory lyase activity required to remove the backbone of an AP site (i.e., deoxyribose) during base excision repair.

Helix-hairpin-helix (HhH) The HhH structural motif binds single- or double-stranded DNA in a

non-sequence-specific manner and has been identified in a number of DNA repair proteins. Two such motifs in pol β are observed to make DNA backbone interactions with the incised DNA strand downstream and upstream of the gap, suggesting that they stabilize the pronounced DNA bend observed when gapped DNA binds to pol β .

Lyase In the context of single-nucleotide base excision repair, this reaction results in the removal of the 5'-deoxyribose phosphate backbone after incision of an AP site by an endonuclease. The reaction proceeds by β -elimination through a Schiff base intermediate. The ϵ -NH₂ group of a lysine side chain (Lys72 of pol β) serves as a nucleophile resulting in transient covalent attachment of the enzyme to its substrate. This Schiff base intermediate can be trapped by sodium borohydride, resulting in conversion to an irreversibly linked lyase-DNA complex.

N-subdomain One of the three subdomains found in all DNA polymerases. This subdomain forms one face of the nascent base pair (templating and incoming nucleotide bases) binding pocket and it is involved in selecting the correct deoxynucleotide triphosphate. It is also referred to as the fingers subdomain in the polymerase nomenclature that utilizes the analogy to a right hand.

Introduction

Endogenous and environmental agents continually threaten cellular DNA. These threats can result in physical damage (e.g., DNA strand breaks or base loss) or modification (e.g., alkylation and cross-links). Since these genetic insults lead to an altered DNA structure that can result in deleterious outcomes, cells have evolved DNA repair mechanisms to correct these abnormalities. The base-excision repair (BER) pathway is responsible for removing simple base lesions and AP sites in DNA. The repair of an AP site minimally requires four coordinated enzymatic activities: strand incision by AP endonuclease, removal of the resulting deoxyribose phosphate (dRP) backbone of the AP site by a pol β -associated lyase, single-nucleotide DNA synthesis by pol β , and ligation of the DNA nick by DNA ligase. These steps are illustrated in [Figure 1](#).

Pol β is the smallest eukaryotic cellular DNA polymerase (335 residues; 39 kDa) and it lacks a proofreading 3'→5' exonuclease activity that enhances the accuracies of replicative DNA polymerases (e.g., DNA polymerase ϵ and δ). Based on primary sequence alignments, pol β belongs to the X-family of DNA polymerases that also includes pol λ and pol μ .

Biological Role

Based upon the high level of sequence conservation of pol β among mammalian species, it seemed highly likely that pol β is conducting a role that is essential for animal survival. This is consistent with the embryonic lethality of pol β null mice. Pol β preferentially fills short DNA gaps (<6 nucleotides). Because of this attribute, it had generally been assumed that pol β is involved in short-gap DNA repair synthesis. In addition, early studies implicated pol β in gap-filling DNA synthesis during mammalian BER of alkylation damage and the repair of ultraviolet (UV) DNA damage, and inhibitor studies also implicated pol β in other types of DNA repair, such as the repair of oxidative DNA damage. Although these attributes and studies implicated pol β in BER and in other types of short-gap-filling DNA repair, pol β 's role in BER was confirmed when mouse cells lacking pol β were found to be hypersensitive to DNA-damaging agents believed to be repaired by the BER pathway.

In addition to the simple single-nucleotide BER pathway illustrated in [Figure 1](#), alternate BER pathways are needed to remove modified dRP moieties that cannot be excised by the pol β lyase activity. In this situation, pol β strand displacement

DNA synthesis creates a DNA flap of several nucleotides with a 5'-modified dRP group that can be subsequently removed by flap endonuclease-1 (FEN-1), thereby creating a nick that will be sealed by DNA ligase. This alternate pathway is referred to as 'long-patch' BER. In the absence of strand displacement DNA synthesis, FEN-1 incision excises the dRP group and one nucleotide, thereby creating a one-nucleotide gap that will be filled by pol β . Alternating single-nucleotide gap-filling DNA synthesis and FEN-1 activities can create a long BER patch and has been referred to as 'hit and run'.

Figure 1 Single-nucleotide base excision repair. AP sites are lesions in DNA that originate from spontaneous or enzymatic (glycosylase) removal of a damaged base (large red circle). These sites are removed from DNA by four coordinated enzymatic activities, two of which are contributed by pol β (blue); DNA synthesis and dRP lyase that occur concurrently.

Pol β Domain Organization

Controlled proteolytic or chemical cleavage of pol β first demonstrated that it is folded into discrete domains. Subsequently, the X-ray crystal structure of the ternary substrate complex with DNA and an incoming nucleoside triphosphate (dNTP) defined the location of these domains in relation to the tertiary structure of the polymerase. Pol β is organized into two domains: an 8-kDa amino-terminal lyase domain and a 31-kDa carboxyl-terminal polymerase domain (Figure 2).

The structures of DNA polymerases derived from other polymerase families indicate that they also have a modular domain organization. The polymerase domain is typically composed of three functionally distinct subdomains. The catalytic subdomain coordinates two divalent metal cations that promote DNA synthesis. The other two subdomains are spatially situated on opposite sides of the catalytic subdomain. Based on an architectural analogy to a right hand, the subdomains are referred to as palm, thumb, and fingers. To highlight the intrinsic function of the polymerase subdomains of pol β , a functionally based nomenclature has been proposed. Accordingly, the pol β polymerase domain is composed of C- (catalytic), D- (duplex DNA binding), and N-subdomains (nascent base pair binding) (Figure 2). These correspond to the palm, thumb, and fingers subdomains employing the right-hand analogy.

Lyase Domain

The amino-terminal lyase domain (residues 1–90) has an associated lyase, metal-independent, activity that removes the 5'-dRP moiety generated during single-nucleotide BER (Figure 1). This activity plays a pivotal role in BER in that if the lyase reaction is inhibited (e.g., modified dRP moiety),

Figure 2 Domain and subdomain organization of pol β . (Left) A ribbon representation of pol β illustrating the polymerase (colored) and amino-terminal lyase (gray) domains (PDB code 2FMS). The polymerase domain is composed of three subdomains: D, magenta; C, light blue; and N, purple. These correspond to the thumb, palm, and fingers subdomains of DNA polymerases that utilize an architectural analogy to a right hand, respectively. Lys72 of the dRP lyase active site is indicated (blue), as well as the catalytic Mg^{2+} required for DNA synthesis (green sphere). (Right) The molecular surface of pol β with single-nucleotide gapped DNA and incoming nucleoside triphosphate substrates. The template strand is orange and the upstream and downstream portions of the incised strand are yellow. The duplex DNA is illustrated in a ladder representation with the nascent base pair (templating nucleotide and incoming nucleoside triphosphate) delineated with a white dashed parallelogram. The lyase domain and the D-subdomain each have a HhH motif (not shown) that interacts with the DNA backbone of the incised DNA strand downstream and upstream of the gap, respectively.

alternate BER pathways will be initiated. The lyase reaction proceeds by β -elimination through a Schiff base intermediate. A stable covalently bound intermediate can be formed between the dRP-containing DNA substrate and the enzyme by NaBH_4 trapping. Lys72 is preferentially modified by primary amine reactive agents in both full-length pol β and the isolated lyase domain. Site-directed mutagenesis of Lys72 diminishes dRP lyase activity nearly two orders of magnitude, indicating that this residue is the likely nucleophile that forms the Schiff base intermediate. The lyase domain is highly basic (net charge = +10), and the positively charged surface potential predicts that it would interact with the DNA backbone.

In addition to providing a crucial enzymatic activity for single-nucleotide BER, the lyase domain possesses a 5'-phosphate binding site that facilitates targeting of pol β into the 5'-position in a DNA gap. Importantly, pol β binds tightly to the 5'-phosphate only when there is DNA adjacent to the 5'-phosphate. This can be double-stranded or single-stranded DNA since a 3'-primer terminus is not required for optimum binding. Accordingly, pol β is expected to bind to the 5'-phosphate in a DNA gap of any size. The observation that pol β can processively (i.e., insert several nucleotides before dissociating from the DNA substrate) fill short gaps (<6 nucleotides) suggests that the lyase domain tethers the polymerase domain to the downstream position in gapped DNA. When the primer terminus (i.e., 3'-OH) is within 6 nucleotides of the 5'-phosphate on the downstream DNA strand, the proximity of the polymerase domain to the primer terminus would hasten processive DNA synthesis.

The lyase domain is composed of five α -helices (Figure 2, left panel). Structural characterization of this domain has identified a structural motif that binds monovalent metals and interacts with the DNA backbone. The helix-hairpin-helix (HhH) motif (residues 55–79) has also been identified in other DNA repair proteins as well as many proteins that bind either single- or double-stranded DNA in a non-sequence-specific manner. The crystal structure of pol β bound to a one-nucleotide gap DNA substrate indicates that the lyase domain and the N-subdomain of the polymerase domain interact (Figure 2). The interaction of the lyase domain and the N-subdomain results in a donut-like structure. The interactions between these subdomains are altered upon binding substrates resulting in a tighter complex.

Polymerase Domain

D-subdomain

The polymerase domain is composed of three functionally distinct subdomains. The lyase domain is connected to the D-subdomain (residues 91–149) with a protease-hypersensitive hinge region. The D-subdomain interacts with the DNA sugar-phosphate backbone of the duplex DNA upstream of the polymerase active site. In addition to the HhH motif found in the lyase domain, a second HhH motif (residues 92–118) is also found in the D-subdomain. This HhH motif interacts with the primer strand phosphate backbone through a monovalent metal ion. Thus, the two HhH motifs in pol β are observed to make DNA backbone interactions with each end of the incised DNA strand. In the crystal structure of pol β bound with an incoming nucleotide and a one-nucleotide

DNA gap, the DNA is bent about 90° (Figure 3, left panel). The DNA template does not travel through the hole in the donut-like structure. The sharp bend occurs at the 5'-phosphodiester bond of the templating base and is also observed in a product complex where pol β is bound to nicked DNA. The 3'-hydroxyl and 5'-phosphate groups on the nicked DNA strand, which needs to be ligated in the final step of BER, are observed to be over 27 Å apart. For pol β , the function of the HhH motifs appears to be a sequence nonspecific phosphate-backbone binding motif that stabilizes the pronounced bend observed in the pol β -gapped DNA structure. The 90° bend also exposes the terminal base pairs of each DNA duplex that is situated in the gap. His34 of the lyase domain interacts with the first base pair of the downstream duplex, whereas the N-subdomain contributes interactions with the nascent base pair (see below). The dramatic bend of the template strand as it enters the polymerase active site is a general feature observed in crystal structures of substrate complexes of most DNA polymerases.

C-subdomain

The C-subdomain (residues 150–261) of pol β includes three acidic residues (Asp190, Asp192, and Asp256) that coordinate two essential magnesium ions. One magnesium coordinates nonbridging oxygens on the three phosphates of the incoming nucleotide (nucleotide-binding metal), whereas the other coordinates oxygens on the α -phosphate of the incoming dNTP and the DNA primer terminus (catalytic metal). These metals are believed to play critical and conserved roles in catalysis (nucleotidyl transfer) in all DNA polymerases. Although the C-subdomains of X-family and bacterial pol III members are not homologous to those of many other polymerase families, crystal structures of substrate complexes of DNA polymerases from other families indicate that the reactive groups (i.e., metals, incoming nucleotide, and DNA) have a similar three-dimensional arrangement. Likewise, all DNA polymerases follow an ordered binding of substrates where DNA binds first. The polymerase then selects a nucleoside triphosphate from a pool of structurally similar molecules to preserve Watson-Crick base-pairing rules. The ability to choose between right and wrong is highly dependent on the identity of the polymerase. Pol β has a moderate ability to select the correct (i.e., right) nucleotide and capacity for DNA synthesis. Since it does not have an intrinsic proofreading activity, it has the potential to be highly mutagenic. The fidelity of pol β is too low (1 error per ~2000 nucleotides synthesized) for pol β DNA synthesis errors to be tolerated during DNA repair. It is generally believed that the proofreading activity of AP endonuclease, or some other extrinsic 3'→5'-exonuclease, may proofread base substitution errors generated by pol β .

N-subdomain

The N-subdomain (residues 262–335) contributes important interactions to the binding pocket of the nascent base pair (templating and incoming nucleotides). Comparison of DNA polymerase structures bound to DNA with those that include an incoming complementary dNTP reveals that the N-subdomain repositions itself to sandwich the nascent base pair between the growing DNA terminus and the polymerase (Figure 3). In the absence of an incoming nucleotide, the N-subdomain is open, but forms a closed complex upon

Figure 3 Nascent base-pair-binding pocket. The perspective is from the major groove edge of the nascent base pair. (Left) The N-subdomain (purple) is shown forming one face of the binding pocket for the new base pair (i.e., templating nucleotide and incoming nucleoside triphosphate). The lyase and C- and D-subdomains are not shown for clarity. The 5'-end of the template strand (orange) is indicated. The complementary DNA strands (primer and downstream oligonucleotides) are yellow. The trajectory of the template strand is altered dramatically as it enters the polymerase active site at the 5'-phosphodiester bond of the templating nucleotide (white arrow). The active site metals (Mg^{2+}) that coordinate the incoming dNTP and assist catalysis are illustrated as green spheres. (Right, upper panel) Detailed view of the nascent base-pair-binding pocket occupied by a correct base pair. The templating nucleotide (n) binding site (e.g., adenosine) is outlined with a white dashed box. The 3'-OH of the primer terminus (red circle) is in an ideal position to attack $\text{P}\alpha$ of the incoming nucleotide (black arrow). The active site metals (Mg^{2+}) that assist catalysis are shown. Asp276 (D276) and Lys280 (K280) make van der Waals contact with the bases of the incoming and templating nucleotides, respectively. Asn279 and Arg283 form the minor groove edge of the binding pocket. (Right, lower panel) Detailed view of the nascent base-pair-binding pocket during insertion of the wrong nucleotide (dAMPCPP) with a templating guanine (PDB code 3C2M). The active site metals (Mn^{2+} , pink) are shown. In this case, the template pocket (white dashed box) is empty due to an upstream shift in the template strand. The shift in template strand also displaces $\text{O}3'$ (red circle) of the primer terminus deterring misinsertion by altering the geometry (angle and distance) of attack on $\text{P}\alpha$ of the incoming nucleotide (black arrow).

binding a correct nucleotide. Thus, the dNTP-binding pocket is formed by the template base, DNA duplex terminus, and enzyme. For pol β , subdomain interactions with the nascent base pair are contributed primarily through the N-subdomain (Figure 3). These include stacking interactions with Lys280 and Asp276 with the templating and incoming nucleotide bases, respectively. Additionally, Asn279 and Arg283 contribute DNA minor groove interactions. Alanine substitution for Arg283 results in a dramatic decrease in fidelity. Since Arg283 plays a critical role in the formation of the closed complex, the low-fidelity mutant (i.e., R283A) is believed to be in an open conformation that has lost the ability to promote efficient DNA synthesis when a correct nucleotide binds. Thus, the ability to choose the correct nucleotide has been lost. As noted above, the trajectory of the duplex DNA into the polymerase active site requires that the templating strand bends by 90° (Figure 3). This bend in the template strand serves at least two functions: (1) it provides access for the N-subdomain to check whether geometrical constraints imposed by correct Watson-Crick hydrogen bonding occurs and (2) it discourages the next templating base from entering the polymerase active site prematurely which could result in the incorrect template base coding for nucleotide insertion (deletion mutagenesis). The closed polymerase conformation also discourages

misinsertion by removing the templating nucleotide from its coding positions when an incorrect nucleotide binds (Figure 3, bottom right panel). In this situation, the binding of an incorrect incoming nucleotide results in an upstream shift in the template strand near the active site. This serves at least two functions: (1) removes coding/misreading potential with the incoming nucleotide, thereby decreasing the binding affinity of the incorrect nucleotide, and (2) alters the geometry of the primer terminus relative to $\text{P}\alpha$ of the incoming nucleotide that will deter misinsertion. The removal of the templating base from its coding position has been compared to that of insertion of a nucleotide, typically dATP, opposite an abasic site. It remains to be seen whether this is a general or alternate strategy to optimize polymerase fidelity.

Pol β -BER-Protein Interactions

In addition to its catalytic function, pol β also interacts with several proteins known to be involved in BER. These interactions may facilitate the coordination of the necessary enzymatic steps required in alternate BER pathways. In this context, the observations that pol β interacts with other DNA repair proteins such as AP endonuclease, DNA ligase I, X-ray

cross-complementing factor-1 (XRCC1), poly(ADP-ribose) polymerase-1 (PARP-1), and proliferating cell nuclear antigen (PCNA), among others, suggest complex regulatory mechanisms that are not fully understood. Thus, pol β interacts with the enzymes involved in the steps immediately upstream and downstream of its own steps in single-nucleotide BER. Importantly, the formation of binary or ternary protein complexes, rather than a super BER complex, has the advantage of flexibility that can accommodate alternate pathways. The influence of these protein–protein interactions on catalytic function and processing of BER intermediates remains to be determined.

Glossary

Apo-enzyme Enzyme in the absence of bound substrates.

Mispair Two opposed bases in DNA that do not conform to the Watson–Crick rules of complementarity, that is, not A–T or G–C.

Primer In duplex DNA, the strand that presents a 3' end for extension by a DNA polymerase.

Template In duplex DNA, the strand that is paired with the primer, and, therefore, provides the information for copying by DNA polymerase.

Introduction

DNA polymerase I (Pol I) is the most abundant DNA polymerase in eubacteria. Although it lacks the speed and processivity of the more complex polymerases which replicate the bacterial chromosome, it is ideally suited for the synthesis of short stretches of DNA in excision repair and in the removal of RNA primers during lagging strand replication. DNA Pol I of *Escherichia coli*, the first DNA polymerase to be discovered and studied, has long served as the prototype for this class of enzymes. Klenow fragment, which contains the polymerase activity of Pol I, was the first polymerase to be studied crystallographically. Subsequently, Klenow fragment and its homologs from bacteriophage T7 and the thermophiles *Thermus aquaticus* (*Taq* DNA pol) and *Bacillus stearothermophilus* (*Bst* DNA pol) have provided a wealth of informative co-crystal structures that are the foundation for our current understanding of the DNA polymerase reaction mechanism.

Overview of Structure

Bacterial Pol I enzymes are multifunctional and follow the pattern seen throughout the polymerase superfamily: a modular structure with a common polymerase domain (described below) and auxiliary enzyme activities located on separate protein domains. All bacterial Pol Is have an N-terminal domain with 5' nuclease activity; this activity is responsible for the removal of DNA ahead of the growing primer strand. Attachment of the 5' nuclease domain to the rest of the polymerase is protease sensitive; in *E. coli* Pol I, mild protease digestion was originally used to remove the 5' nuclease (35 kDa) from the remainder of the molecule (Klenow fragment, 68 kDa); subsequently, this was accomplished by recombinant DNA manipulations. The linkage between the 5' nuclease and Klenow fragment is almost certainly flexible, as shown by the observation that the 5' nuclease does not occupy the same position relative to the rest of the molecule in different crystal forms of *Taq* DNA pol. The Pol I homologs found in bacteriophage genomes resemble the Klenow fragment portion of the bacterial Pol Is, in that they lack the 5' nuclease portion of the sequence. In some cases, such as bacteriophage T7, the 5' nuclease is encoded as a separate gene product.

The Klenow fragment portion of Pol I also contains two domains. In about half of the bacterial Pol Is, the N-terminal of the two domains contains a 3'–5' exonuclease (3' exo) activity, which serves as a proofreader to eliminate polymerase errors. If the polymerase were to insert an incorrect nucleotide, resulting in a terminal mispair, the 3'–5' nuclease would remove the incorrect primer-terminal nucleotide and provide a second opportunity for correct insertion. Those bacterial Pol I enzymes that lack 3'–5' exonuclease activity (from species including *Thermus*, *Bacillus*, and *Rickettsiae*) nevertheless contain the domain, though key active site side chains are absent. Aside from the thermophiles, where fraying of double-stranded DNA termini at high temperatures might encourage excessive nuclease degradation, it is unclear why certain bacterial Pol I enzymes have proofreading activity and others do not.

Based on the sequence of their polymerase domains, the bacterial Pol Is are placed in the A-family, which also includes some bacteriophage DNA polymerases as well as the mitochondrial DNA polymerase gamma and two eukaryotic nuclear DNA polymerases, ν (nu) and θ (theta).

Polymerase

Domain Structure and Relation to Other Polymerases

When the structure of Klenow fragment was reported in 1985, the polymerase domain structure was described as resembling a half-open right hand, with subdomains called 'fingers', 'palm', and 'thumb' forming a cleft. Currently, structures are available for over 60 polymerases, encompassing all four biochemical categories of polymerase (DNA- or RNA-dependent, with DNA or RNA as product), and five of the six families of DNA-dependent DNA polymerases (as defined by protein sequence alignments). It is clear that the overall polymerase domain structure originally observed in Klenow fragment is a common theme (Figure 1), though a detailed examination reveals two distinct polymerase lineages which can be recognized by the structure of the palm subdomain. The larger group, comprising all polymerases except the DNA polymerase families C and X, contains a highly conserved structural motif (the polymerase fold) consisting of a three-stranded antiparallel β -sheet supported by two α -helices. This serves as the scaffold for important active site residues, in particular a pair of

Figure 1 Three-dimensional structure of the polymerase domain of *E. coli* DNA polymerase I. The thumb and fingers subdomains are colored green and blue, respectively, with the O-helix on the fingers subdomain in purple. The palm subdomain is gray, except for the polymerase fold, a conserved structural motif found in the majority of nucleic acid polymerases, which is shown in red. Three conserved carboxylate side chains, two of which are ligands to the catalytic metal ions, mark the location of the polymerase active site. From Brautigam CA and Steitz TA (1998) Structural and functional insights provided by crystal structures of DNA polymerases and their substrate complexes. *Current Opinion in Structural Biology* 8: 54–63.

carboxylate ligands to the two divalent metal ions that catalyze the phosphoryl transfer reaction. The fingers and thumb subdomains are structurally much more divergent between polymerase families, but carry out analogous functions in all polymerases – the fingers providing important active site residues, particularly those involved in nucleotide binding, and the thumb binding the primer–template duplex.

Substrate Binding

The binding of substrates at the polymerase active site has been revealed in co-crystals of several Pol I homologs. The template–primer duplex (corresponding to the product of DNA synthesis) is bound in a shallow cleft between the thumb and 3′ exo domains, with the largely α -helical thumb providing important binding contacts to the phosphate backbone. In a polymerase–DNA binary complex, the primer terminal base pair abuts the side of the polymerase cleft formed by the fingers subdomain. This wall, which defines one side of the active site, is formed primarily by a long α -helix (the O-helix, shown in purple in **Figure 1**), which runs the length of the fingers subdomain and has a group of important and highly conserved side chains on the surface pointing into the cleft. At the C-terminus of the O-helix is an invariant Tyr side chain, which is stacked against the template side of the terminal base pair.

When the deoxyribonucleotide triphosphate (dNTP) complementary to the templating position is added so as to form a polymerase–DNA–dNTP ternary complex, co-crystal structures indicate that the polymerase must have undergone a conformational change (**Figure 2**). The novel conformation seen in ternary complex structures differs from the apo-enzyme and binary complex structures by a substantial movement of a segment of the fingers subdomain so as to close the polymerase cleft. In conjunction with the transition from the open (binary complex) to closed (ternary complex) conformation, the Tyr side chain at the C-terminus of the O-helix moves further down

Figure 2 (a) Superposition of binary (Pol–DNA) and ternary (Pol–DNA–dNTP) complexes of the Klenow-fragment-like portion of *Bst* DNA pol. The DNA template (dark blue) and primer (cyan), incoming nucleotide (red) and active site metal ions (orange) are shown in their positions in the ternary complex. The protein backbone in the binary complex is gray, and the ternary complex green. The two protein structures are essentially superimposable except for a segment of the fingers subdomain that includes the O-helix (shown in black and dark green, respectively). The domain marked Exo corresponds to the 3′–5′ exonuclease domain in Klenow fragment, though it has no enzymatic activity in *Bst* DNA pol. (b) Detailed comparison of the active site regions in the two complexes. In each case, the protein is shown in gray, with the O-helix in black. Coloring of the DNA, nucleotide, and metal ions is the same as in the top panel. The structures are oriented so that the palm subdomain and the DNA are in similar positions in both panels, emphasizing the movement of the O-helix. The side chain of the conserved Tyr at the C-terminus of the O-helix (Tyr714 in *Bst* DNA pol, Tyr 766 in Klenow fragment) is shown in green. This side chain is stacked with the template side of the terminal base pair in the binary complex; in the ternary complex, it has moved out of the way to allow the next template base to enter the active site (note that this template base is bound in a pocket between the O and O₁ helices in the binary complex). For clarity, the top of the thumb subdomain is omitted in all the structures illustrated in this figure. From Johnson SJ, Taylor JS, and Beese LS (2003) Processive DNA synthesis observed in a polymerase crystal suggests a mechanism for the prevention of frameshift mutations. *Proceedings of the National Academy of Sciences of the United States of America* 100: 3895–3900.

into the active site, away from its stacked position with the terminal base pair. This allows the templating base to stack with its 3′ neighbor at the duplex terminus, and to base pair with the incoming dNTP in a snug binding pocket formed by side chains of the O-helix and nearby residues on one side, and the primer-terminal base pair on the other side. Analogous conformational transitions have been inferred from crystal

Figure 3 Mechanism of phosphoryl transfer, resulting in nucleotide addition, at the polymerase active site. Catalysis is mediated by two divalent metal ions, coordinated, in Klenow fragment, by Asp705 and Asp882. Metal ion A activates the primer 3'-OH for nucleophilic attack on the α -phosphate of the dNTP. Metal ion B stabilizes the negative charge that develops on the pyrophosphate leaving group. Both metal ions also assist the reaction by stabilizing the negative charge on the α -phosphate in the pentacovalent transition state. Reproduced from Brautigam CA and Steitz TA (1998) Structural and functional insights provided by crystal structures of DNA polymerases and their substrate complexes. *Current Opinion in Structural Biology* 8: 54–63.

structures of a diverse variety of polymerases, suggesting that the formation of a closed ternary complex may be an important feature of the polymerase reaction pathway.

DNA Polymerase Reaction Mechanism

Extensive work by Benkovic and co-workers initially defined the polymerase reaction pathway of Klenow fragment. There is an obligatory order of substrate binding – DNA before dNTP – as would be expected, given that templating information is required for nucleotide selection. As mentioned above, the chemical step of dNTP addition is catalyzed by two divalent metal ions coordinated at the active site (Figure 3). One metal ion facilitates deprotonation of the primer 3'-OH, making it a better nucleophile, while the other stabilizes the pyrophosphate leaving group. Both metals also stabilize the developing negative charge on the α -phosphate in the transition state. This two-metal-catalyzed reaction mechanism is beautifully illustrated in the ternary complex co-crystal structures, and is

widespread in phosphoryl transfer reactions, including the 3'-5' exonuclease reaction (discussed later). The work of Benkovic and colleagues indicated that the phosphoryl transfer step is rapid, but is preceded and followed by slow noncovalent steps. Subsequent studies, using fluorescence as a reporter of conformational transitions, have identified at least two noncovalent steps that precede phosphoryl transfer. These steps, which include the fingers-closing transition, are not observed in the presence of a mispaired dNTP, implying the existence of early specificity-determining steps, which reject mispaired dNTPs or other inappropriate substrates.

More recently, the application of single-molecule fluorescence techniques to Klenow fragment has allowed observation of processes previously obscured when observing large populations of molecules in traditional ensemble kinetic studies. For example, we now know that, in the absence of bound substrates, the unliganded polymerase explores the same conformational motions that are used in the reaction pathway. In another study, observations of single Klenow fragment molecules copying a tethered DNA molecule have demonstrated the effects of local DNA sequence and secondary structure on polymerase behavior and emphasized the stochastic nature of processive DNA synthesis.

DNA Polymerase Reaction Specificity

Base pairing

DNA polymerases function with extraordinary specificity, selecting the complementary dNTP and rejecting incorrect choices in the majority of cases. Klenow fragment makes approximately one error for every 10^5 nucleotides synthesized, about 1000-fold more accurate than would be predicted solely from the energetics of base pairing. Three major mechanisms have been proposed to account for the way in which the polymerase enhances the accuracy of DNA synthesis. The first is exclusion of water from the active site, which should amplify the energetic differences between correct and incorrect base pairings. The second is geometric selection in the binding pocket for the nascent base pair, such that there is good steric complementarity to the rather symmetrical shape of a Watson–Crick base pair, but exclusion of mispairs. This model is consistent with the very snug fit seen in the binding pocket of polymerase ternary complex structures. Moreover, a variety of polymerases, including Klenow fragment, incorporate template–primer pairings that mimic the shape of a Watson–Crick base pair but lack any hydrogen bonds. The first two specificity mechanisms are proposed to operate at the level of nucleotide addition and would be expected to weaken the binding and/or slow the incorporation of an incorrectly paired incoming nucleotide. As mentioned earlier, a mispaired dNTP affects early steps of the polymerase reaction pathway, well before the chemical step of nucleotide addition. Any proposed selection mechanism would therefore come into play at an early fidelity checkpoint, most probably preceding the fingers-closing conformational change, so that specificity models based solely on the geometry of the binding pocket are too simplistic. Indeed, there is increasing evidence for a hypothetical preview step, in which the incoming dNTP is tested for complementarity to the templating base, before fingers-closing.

The third selection method would operate after nucleotide addition and relies on hydrogen-bonding interactions between the polymerase and the minor groove at or close to the primer terminus. The hydrogen bond acceptors on N₃ of purines and O₂ of pyrimidines occupy similar positions in all Watson–Crick base pairs, but are mispositioned in incorrect pairings, thus providing a mechanism for scanning the minor groove to ensure that template information has been correctly read. A mispair located at the primer terminus will fail to make the minor groove interactions that are seen for correct base pairs in polymerase co-crystal structures and this, together with other geometric abnormalities, results in a much slower rate of addition of the next nucleotide. Slower polymerase addition to a mispaired primer terminus reduces the likelihood of a mispair becoming fixed as a mutation by continued synthesis, and also increases the time window during which the error may be proofread, or the mispaired DNA may dissociate.

As might be expected from the different geometries of various mispairs, a polymerase such as Klenow fragment does not make all errors at the same frequency; for example, insertion of dGTP opposite a template T is relatively facile, whereas insertion of dCTP opposite C is rare. Klenow fragment mutator mutants change not only the frequency of errors but also the specificity, and their study provides a valuable window into the recognition processes that take place at the polymerase active site.

Sugar specificity

Bacterial Pol Is also have stringent specificity for the sugar of the incoming nucleotide. A DNA polymerase must reject ribonucleotides, despite their higher concentration *in vivo*, and this is achieved by an invariant Glu residue (the ‘steric gate’) whose position in the closed polymerase–DNA–dNTP ternary complex is incompatible with any substituent on the C2′ position of the sugar. Mechanistically, an incoming ribonucleotide triphosphate (rNTP) affects the rate and extent of the fingers-closing step, as expected from the structural description. Mutation of the steric gate Glu to the smaller Ala in Klenow fragment results in a polymerase that can add a ribonucleotide almost as easily as a deoxyribonucleotide. However, the mutant enzyme does not function as a true RNA polymerase because it cannot efficiently add multiple ribonucleotides, most probably because the duplex binding site cannot accommodate a DNA–RNA product.

Pol I enzymes fall into two classes regarding their handling of nucleotide analogs which lack the sugar 3′ hydroxyl (dideoxy nucleotides) and therefore function as chain terminators. The majority, exemplified by Klenow fragment, discriminate very strongly against dideoxy nucleotides. The ternary complex co-crystal structures show a hydrogen bond between the 3′ hydroxyl and the β-phosphate of the incoming nucleotide; presumably, the loss of this interaction compromises the alignment of reactive groups in the transition state, resulting in a slower reaction rate. A minority of Pol Is, exemplified by T7 DNA pol, discriminate only slightly against dideoxy nucleotides. In these polymerases, a conserved aromatic side chain that forms part of the nucleotide-binding pocket is present as Tyr, instead of the more usual Phe, and the Tyr hydroxyl provides the missing interaction with the

β-phosphate. The ability to manipulate chain-terminator specificity via a single active-site point mutation has proved to be invaluable in DNA sequencing and related biotechnology applications.

3′–5′ Exonuclease

The 3′–5′ exonuclease, present in about half of Pol Is, carries out its editing function by means of hydrolysis of the terminal nucleotide of the DNA primer strand. The hydrolysis reaction is a phosphoryl transfer, analogous to that described above for the polymerase reaction (Figure 3), catalyzed by a pair of metal ions liganded by a cluster of conserved carboxylate side chains. The other important component of the 3′ exo site is a binding site for single-stranded DNA. In model studies, the exonuclease can be studied using single-stranded DNA as the substrate, though the natural substrate *in vivo* is a duplex DNA whose primer terminus is frayed so as to present three or four bases of single-stranded DNA for binding at the 3′ exo site. The requirement for fraying in order to bind at the 3′ exo active site provides the specificity for editing, because a mismatched primer terminus is more easily melted and is therefore a better substrate for the 3′ exo than a correctly paired DNA. Whereas a correctly paired DNA duplex is bound predominantly at the polymerase site of Klenow fragment, a single terminal mismatch results in ≈50:50 partitioning between polymerase and 3′ exo sites. The preference of the 3′ exo for a mispaired substrate is amplified by the slowing of the polymerase reaction caused by a mispaired primer terminus (discussed earlier), so that a mispair is likely to be targeted for proofreading, while a correct primer terminus will serve as a substrate for continued addition.

The contribution of proofreading to polymerase fidelity is quite variable in the Pol Is. As already noted, some Pol Is do not proofread at all. In others, such as *E. coli* Pol I, the contribution of proofreading is relatively modest, about 10-fold. Others, such as the polymerases from bacteriophages T5 and T7, have more active exonucleases. Additionally, depending on the strength of the polymerase–DNA interaction, the DNA may stay associated with the polymerase during the transfer from polymerase to editing site, as in T5 and T7, or it may reach the proofreading site via dissociation from the polymerase site and binding to the exonuclease site of another enzyme molecule. As the selectivity of editing is determined simply by the structure of the DNA substrate (paired or mispaired) and does not require a particular mode of presentation of the primer terminus by the polymerase, the intermolecular transit from polymerase to exonuclease site would not be expected to compromise the editing process.

5′ Nuclease

The 5′ nuclease of the bacterial Pol I enzymes was described as the ‘5′–3′ exonuclease’ in the earlier literature. However, it is now recognized that this activity is not a true exonuclease, but is a structure-specific nuclease that recognizes the junction between duplex DNA and a single-stranded 5′ end, and cuts between the first two paired bases (Figure 4(a)). The 5′

Figure 4 (a) Site of cleavage by the 5' nuclease on a model substrate containing noncomplementary 5' and 3' extensions. The nuclease cuts between the first two paired bases. (b) The polymerase and 5' nuclease activities collaborate in processing a DNA molecule with a 5' single-stranded tail so as to produce a nicked product that can be sealed by DNA ligase. Cleavage of the first structure, between the first two paired bases adjacent to the 5' tail, would yield a single-base gap. Nucleotide addition by the polymerase (in red), together with the preference of the 5' nuclease for a melted base at the 3' end of the adjacent primer strand, favors the formation of a ligatable product.

nucleases present in bacterial Pol Is are related to a larger family of autonomous structure-specific nucleases, or flap endonucleases (FENs), found in bacteria, bacteriophages, eukaryotes, and archaea.

The 5' nuclease of Pol I cooperates with the polymerase when acting on a nicked DNA molecule; nucleotide addition by the polymerase causes strand displacement which generates the substrate for the 5' nuclease, so that the net result is nick translation, the movement of a nick along a duplex DNA molecule. DNA-binding experiments show that the polymerase and 5' nuclease compete for binding to a DNA substrate; this implies a mechanism in which the DNA is passed from one active site to the other, and rules out mechanisms in which both reactions take place within a single bound species. The preferred substrate for the 5' nuclease has, in addition to the unpaired 5' strand, an unpaired base at the 3' end of the primer

strand abutting the ss-ds junction. This substrate could be formed by rearrangement of the product of polymerase extension and, when cleaved by the 5' nuclease, will leave a junction ready for ligation (see [Figure 4\(b\)](#)). The observed specificity of the 5' nuclease fits well with the *in vivo* functions of the bacterial Pol I enzymes in DNA repair and in the removal of primers from Okazaki fragments on the lagging strand. In both cases, the desired end point of Pol I action is a nick that can be sealed by DNA ligase.

Several 5' nuclease structures have been solved in the absence of substrates, and two co-crystal structures with bound DNA show the architecture of the enzyme-substrate complex. The 5' nuclease active site contains a large number of conserved carboxylate residues, inviting speculation that, like the polymerase and 3'–5' exonuclease activities, the 5' nuclease catalyzes phosphoryl transfer using bound divalent metal ions. However, where metal ions are present in 5' nuclease or FEN structures, the metal-to-metal distances are larger than would be appropriate for a simple two-metal-ion mechanism analogous to that shown in [Figure 3](#) (which requires a metal-to-metal distance of <4 Å). It is therefore possible that the 5' nuclease mechanism may differ from the polymerase and 3'–5' exonuclease reactions by requiring the direct participation of active-site side chains in the phosphoryl transfer process, and further studies will be needed to clarify this question.

Glossary

AAA+ ATPase family An extension of the AAA (for ATPases associated with a variety of cellular activity) family, originally defined to include proteins with a common ~200-residue ATPase core.

Mismatch repair A class of DNA repair that corrects mispairs and small bulge structures in DNA, which are caused mainly by replication errors.

Mutator A phenotype showing an increased rate of spontaneous mutation, which is caused by a mutation

within one of the genes for maintenance of replicational fidelity or repair of spontaneous damage to DNA and substrate nucleotides.

Nucleotide excision repair A class of DNA repair by which a segment of DNA containing lesions is excised and replaced with resynthesized DNA.

Translesion DNA synthesis A cellular process involving specialized DNA polymerases that counteract the replication-blocking damage to DNA.

Replicative Apparatus in Bacterial Cells

In bacterial cells, the circular chromosome contains a unique origin, and DNA replication proceeds bidirectionally from the origin to the terminus. Replication of the whole bacterial genome (4700 kb for *Escherichia coli* (*E. coli*)) is continuous from the origin to the terminus, and is accompanied by movement of the replicating point, called the replication fork. Both parental DNA strands are concurrently replicated at the fork. As DNA polymerase can extend a DNA chain only in the 5'→3' direction, replication at a fork is semi-discontinuous: DNA synthesis is continuous on one strand (the leading strand) and discontinuous on the other (the lagging strand). Short pieces of DNA, called Okazaki fragments, are repeatedly synthesized on the lagging-strand template. These Okazaki fragments are a few thousand nucleotides long in bacterial cells.

DNA replication is a complex process, involving numerous enzymes at the replication fork. In *E. coli*, more than 20 different proteins participate in DNA replication. Among these proteins, DnaB, DnaG, and Pol III HE are the three basic components acting at the replication fork, forming a multiprotein complex called the replisome (Figure 1). The DnaB protein is a major replicative DNA helicase which moves along the lagging strand in the 5'→3' direction and opens up the duplex DNA at the tip of the replication fork to expose a pair of single-stranded DNA templates. The DnaG protein is a primase which synthesizes a short RNA to prime DNA chain elongation catalyzed by Pol III HE.

The highly organized and remarkably efficient process needed for replicating chromosomal DNA is achieved by physical and functional interactions among these three components. Pol III HE associates with DnaB protein and pushes the helicase forward as it proceeds along the leading strand. Thus, the velocity of replication fork movement is determined mainly by the rate of chain elongation by Pol III HE, about 1000 bp s⁻¹. DnaB interacts with DnaG and activates cyclically the primase activity as the helicase moves along the lagging strand, resulting in timely initiation of Okazaki fragment

synthesis. Finally, the proper recruitment of Pol III HE to the replisome requires an RNA primer formed within the origin and, thus, depends upon the function of DnaG.

In bacterial cells, Pol III HE and the other components of the replisome localize to discrete positions, predominantly at or near the midcell throughout the cell cycle. It is considered that the DNA is threaded through the centrally positioned replisome during duplication, and then extruded from the replisome after duplication.

Subunits and Subassembly of Pol III Holoenzyme

The machine-like action of Pol III HE at the replication fork, far more complex than what is necessary for mere DNA polymerization, is based on its subunit structure. Ten different polypeptides form an isolable 17-subunit Pol III HE complex in *E. coli*. The whole assembly is very stable while participating in the replisome at the replication fork. However, during the course of purification, Pol III HE readily disassembles into free subunits and various subassemblies, analyses of which have greatly helped clarify the biochemical function of each subunit and the architecture of the holoenzyme (Figure 2). Smaller numbers of subunits assemble to form the holoenzyme in *Bacillus subtilis* and other bacterial species, although the basic architecture is conserved in most bacteria.

Pol III Core

The α subunit, the largest polypeptide among the holoenzyme subunits, is the heart of the enzyme in the form of DNA polymerase. It exhibits DNA polymerase activity and forms a catalytic core subassembly, called Pol III core, with one molecule each of the ϵ and θ subunits. The α subunit has a characteristic structure, with a right-hand shape composed of palm, thumb, and finger domains, which is common in all other types of DNA polymerases. In the palm domain, as in other DNA polymerases, the α subunit has the polymerase

Figure 1 The replication fork and three basic components of the replicative apparatus in bacteria.

Figure 2 A schematic view of the architecture of DNA polymerase III holoenzyme.

motif, an amino acid sequence motif, which consists of six segments each containing 5–10 residues. The polymerase motif corresponds to catalytically important structural determinants for the active center of DNA polymerases.

Although the basic structure of DNA polymerases is conserved, the DNA polymerases are classified into six families, A, B, C, D, X, and Y, according to their structural similarity. All the catalytic subunits of replicative DNA polymerases in eukaryote, archaea, and bacteriophage belong to the family B,

while the α subunit of Pol III belongs to a distinct family, family C. The family C DNA polymerase is more closely related to the family X, which is known as a member of the human Pol β -like nucleotidyltransferase superfamily, rather than the family B. In contrast to the family B DNA polymerases, the α subunit of Pol III lacks the 3'→5' exonuclease activity required for the proofreading function, which removes nucleotides that have been incorrectly inserted by the polymerase. In addition, the α subunit is a distributive enzyme and it can extend fewer than 10 nucleotide residues for each DNA-binding event.

Despite the feeble activity of the α subunit, Pol III core has high catalytic efficiencies for DNA synthesis and proofreading. This is achieved by forming a complex with other subunits. In the Pol III core, the ϵ subunit acts as the editing exonuclease together with the θ subunit and ensures highly accurate DNA synthesis by the polymerase. Cells that are defective in ϵ subunit function show a strong mutator phenotype, with remarkably elevated frequencies of spontaneous mutation. Despite the catalytic activity of Pol III core being higher than that of the α subunit, the subassembly has limited processivity of DNA synthesis due to its low affinity to template DNA. Other subunits, especially the β subunit, greatly enhance and regulate the processivity of the core.

τ Subunit and Pol III'

The τ subunit is the second largest subunit and forms a stable homodimer complex when it is free in solution. An important function of the τ subunit is to make the Pol III core into a dimer. The C-terminal domain of the τ subunit interacts with the α subunit, and the dimeric nature of the τ subunit itself facilitates dimerization of the Pol III core. The resulting subassembly, called Pol III', consists of two Pol III cores and two τ subunits. The τ subunit improves the low processivity displayed by the Pol III core, resulting in a moderately increased processivity for Pol III'.

Besides dimerization of the Pol III core, the τ subunit plays multiple roles at the replication fork. In the HE complex, the τ dimer forms bridges between dimeric polymerases and other auxiliary subunits. In addition, as a scaffold of the replisome, the τ dimer connects Pol III HE and the DnaB helicase at the replication fork.

β Subunit and Pol III*

Among the holoenzyme subunits, the β subunit is the one that most easily dissociates from the holoenzyme complex. Phosphocellulose or cation-exchange column chromatography effectively separates the holoenzyme into the β subunit and Pol III*, a subassembly that retains all the subunits except β . However, the association of the β subunit with Pol III* is very stable when it forms a ternary complex with template-primer DNA.

The β subunit is a crescent-shaped polypeptide, and it forms a homodimer with a doughnut-like structure which encircles double-stranded DNA and slides along the DNA. The β dimer binds to the α subunit, even in the absence of other HE subunits, and it tethers the α subunit to template DNA during DNA synthesis. The ability of Pol III HE to perform highly processive DNA synthesis is based on the sliding-clamp nature of the β subunit and the α - β interaction. The β subunit also interacts with the δ subunit in an adenosine triphosphate

(ATP)-dependent manner when β is functioning in the HE complex. Albeit much more weakly than its interaction with the α subunit, the β dimer can associate with other proteins including all the other *E. coli* DNA polymerases, a mismatch repair protein (MutS), DNA ligase, and a replication-initiator protein (DnaA). Involvement of the β subunit in many aspects of DNA transactions other than DNA replication has been suggested.

Pol III*, the largest subassembly of Pol III HE, consists of two Pol III cores, two molecules of τ subunit, and one molecule

each of the γ , δ , δ' , χ , and ψ subunits. The architecture of Pol III* is semi-symmetrical. As in Pol III', the τ dimer connects two Pol III cores in a symmetrical configuration. On the other hand, the other five auxiliary subunits impose an asymmetry on the dimeric polymerases. Among these auxiliary subunits, γ , δ , and δ' form a pentameric circular complex (the DnaX complex) with the τ dimer, while the χ and ψ subunits form another complex that bridges the DnaX-complex and the single-stranded DNA-binding protein (SSB).

Figure 3 Concurrent DNA synthesis of leading and lagging strands by the bacterial replisome.

DnaX Complex

The biochemical function of the DnaX complex is to load the β clamp on DNA. The δ subunit directly interacts with the β subunit and opens the β ring. Other subunits assist and regulate the action of the δ subunit. The τ and γ subunits are encoded by the *dnaX* gene and, thus, are called DnaX proteins. τ is the full-length translation product, while γ is a truncated protein that arises by translational frameshifting. Hence, the N-terminal portion of τ is identical to that of the γ subunit. Furthermore, all the subunits of the DnaX complex are structurally related to the AAA+ ATPase family, although only τ and γ show ATPase activity.

ATP binding and hydrolysis of ATP are crucial events for the clamp-loading action of the DnaX complex. In the absence of ATP, the five-subunit circular complex is in a tightly closed configuration, and inert for loading the β subunit. In particular, the δ' subunit blocks the δ subunit's interaction with the β subunit. When all three DnaX proteins in the complex bind ATP, the DnaX complex attains a more relaxed form in which the δ subunit readily gains access to the β subunit. Upon association with the δ subunit, the β ring is opened and mounted on primer-template DNA. Contact between the β -DnaX complex and DNA activates hydrolysis of ATP bound to the DnaX complex, which leads to dissociation of β from the δ subunit, leaving the closed β ring on the primer-template DNA.

Pol III HE in Other Bacteria

Genes encoding the subunits of Pol III HE have been identified in the genomes of many species of eubacteria. Among these genes, those encoding the α , β , τ , δ , and δ' subunits are well conserved, while those for other subunits seem to be significantly divergent or lost. In many bacterial species, the *dnaX* gene does not show an obvious frameshifting signal sequence and, therefore, likely produces only the τ subunit as a single DnaX protein. A group of bacterial species (Gram-positive, G + C low), including *B. subtilis*, *Staphylococcus aureus*, and *Streptococcus pyogenes*, possesses two distinct family C DNA polymerases, both of which are required for chromosomal replication. Despite the apparent diversity among different species, analyses of Pol III HE in bacterial species that are evolutionarily distant from *E. coli* have demonstrated that the basic architecture and biochemical functions of Pol III HE are common throughout the eubacteria.

Concurrent DNA Synthesis of Leading and Lagging Strands

In vitro reconstitution of the replisome with purified Pol III*, β subunit, DnaB helicase, DnaG primase, and SSB has indicated that a single Pol III HE particle can simultaneously

synthesize both leading and lagging strands at a replication fork. Pol III HE is a functionally and structurally asymmetric complex with twin polymerases, one of which participates in leading-strand synthesis and the other in lagging-strand synthesis. The leading-strand polymerase remains continuously clamped to DNA, but the lagging-strand polymerase is repeatedly clamped and unclamped from DNA, to cycle from one Okazaki fragment to the next. As the lagging-strand polymerase is held at the replication fork via the τ -subunit bridge and the leading-strand polymerase, retargeting of the lagging-strand polymerase to the next primer is so efficient and rapid that the overall rate of lagging-strand synthesis matches the rate of leading-strand synthesis (Figure 3).

Pol III HE is initially loaded on the chromosome DNA after the first RNA primer is synthesized within or near the replication origin. One polymerase clamped on the initial RNA primer becomes the leading polymerase, and the other polymerase in the same HE complex serves as the lagging polymerase. An asymmetric arrangement of the DnaX complex in Pol III HE is the basis for the functional asymmetry of the replicative polymerase. It has been hypothesized that the position of the DnaX complex is biased to the lagging polymerase, which limits its clamp-loading activity exclusively to the lagging strand.

Other Biological Functions

Almost all plasmids, and the majority of bacteriophages, use Pol III HE for their DNA replication. Pol III HE is involved in several kinds of DNA transactions that require synthesis of relatively long segments of DNA. These include long-patch nucleotide excision repair, *mutS*-dependent mismatch repair, homologous recombination, and replicative translocation of transposons.

Glossary

Discrimination The ratio of the specificity constant for a correct base pair divided by that for a particular mismatch.

Fidelity The reciprocal of the error frequency; for example, an error frequency of 0.000 002 is expressed as a fidelity of one error in 500 000.

Proofreading exonuclease An exonuclease that removes a single base from the 3' end of the primer strand.

Selectivity The fidelity contribution of individual constants; for example, the selectivity in the ground state binding is

equal to the ratio of the K_d for the incorrect deoxynucleoside triphosphate (dNTP) divided by the K_d for the correct dNTP binding.

Specificity constant The apparent second-order rate constant for nucleotide binding and incorporation, defined by the steady-state kinetic parameters, k_{cat}/K_m , but more accurately measured using pre-steady-state kinetic methods to define k_{pol}/K_d , where k_{pol} is the maximum rate of incorporation and K_d is the apparent ground state nucleotide dissociation constant.

Polymerases can replicate DNA with extraordinary speed and fidelity, copying a template strand at a rate of 300 base pairs per second and making a mistake only one time out of a million. When the polymerase does make a mistake, it stalls by slowing the incorporation of the next correct base pair on top of the mismatch, giving time for a proofreading exonuclease to remove the mismatched base. Selective removal of mismatched bases by the proofreading exonuclease contributes an additional factor of ~ 1000 , resulting in a net fidelity of approximately one error in a billion bases copied. Not all polymerases achieve such high fidelity, however. Rather, each polymerase has evolved a fidelity that balances the biological needs for stability and adaptability. Although the fidelity varies greatly among the polymerases that have been examined in detail, the pathway by which a correct base pair is selected remains invariant. This article briefly summarizes our understanding of the kinetic, structural, and thermodynamic bases governing the fidelity of DNA replication.

Elementary Steps in Polymerization

The free energy difference between a correct and incorrect base pair is quite small ($1\text{--}2\text{ kcal mol}^{-1}$), which leads to a selectivity factor of only 5–30 in favoring the correct base pair over a mismatch. Therefore, the polymerase does not simply stitch together base pairs that form in solution; rather, the fidelity of DNA replication is largely a function of the kinetics of the reactions, involving nucleotide binding, recognition, and incorporation. The polymerase uses not only the base pair free energy but also the base pair geometry in selecting the correct base pair. The new base pair is buried at the active site of the polymerase, shielding it from water molecules, which enhances the free energy difference between correct and incorrect base pairs and facilitates rapid catalysis.

DNA polymerases achieve their extraordinary fidelity by using a two-step nucleotide-binding sequence to select the proper nucleotide for incorporation, as shown in [Figure 1](#).

The deoxynucleoside triphosphate (dNTP) initially binds in a rapid equilibrium reaction to an open state of the enzyme to form the ground state complex (E-DNA-dNTP). A correct base pair enables a change in enzyme structure (at rate k_2) to a closed form in which the active catalytic residues are brought in to the proper orientation necessary for catalysis of the chemical reaction (at rate k_3). This two-step nucleotide-binding sequence is important for two reasons. First, the binding of the nucleotide to the open enzyme form allows a rapid selection of the correct base pair from the four competing nucleotides in solution, using base pair free energy to favor the correct base. Second, the conformational change in the enzyme to the closed form provides additional selectivity dependent upon the proper base pair geometry, and it leads to a close alignment of protein residues around the reactants, shielding them from solvents and bringing about rapid catalysis. A mismatched base pair is discriminated against at each step in the sequence. An incorrect base binds weaker in the ground state, inhibits the rate of the conformational change, and may lead to a misalignment of the reactive groups necessary for catalysis, leading to a much slower rate of incorporation.

Selectivity Contributions of Each Step

Fidelity varies greatly for different DNA polymerases. The DNA polymerase responsible for replicating the viral genome of human immunodeficiency virus (HIV), known as 'reverse transcriptase (RT)' because it copies RNA templates as well as DNA, has a much lower fidelity, making one mistake in only 10 000 base pairs. This higher error rate is essential for the survival of HIV by affording a fast mutation frequency that gives the virus the ability to evade the immune system and all modern drugs, by constantly changing and evolving resistance via the process of natural selection. By contrast, the human DNA polymerase responsible for replicating the mitochondrial genome has an intermediate fidelity, making one error in 300 000; with proofreading, the error frequency is increased to one error in 1.5 million.

Figure 1 Pathway of nucleotide binding and incorporation.

Table 1 Fidelity contributions of ground-state binding and polymerization^a

Polymerase	$K_{d,\text{inc}}/K_{d,\text{cor}}$	$k_{\text{pol,cor}}/k_{\text{pol,inc}}$	Overall fidelity
T7 DNA polymerase	300	5000	1 500 000
Pol γ DNA polymerase	200	1500	300 000
Klenow	170	2300	210 100
Pol β	290	610	19 700
HIV RT	260	50	13 000

^aThe average contribution of ground state binding ($K_{d,\text{inc}}/K_{d,\text{cor}}$) and the maximum rate of polymerization ($k_{\text{pol,cor}}/k_{\text{pol,inc}}$) to the net fidelity are shown for various polymerases, where inc represents an incorrect while cor represents a correct nucleotide, respectively.

Table 2 Kinetics of polymerization

Polymerase	K_d (nM)	k_{pol} (s^{-1})	k_{pol}/K_d ($\mu\text{M}^{-1}\text{s}^{-1}$)	k_{off} (s^{-1})	Processivity	$K_{d,\text{DNA}}$ (nM)
T7 DNA polymerase	18	300	15	0.2	1500	18
Pol γ DNA polymerase	0.8	40	50	0.02	2250	10
Klenow	5	50	5	0.2	250	5
Pol β	10	10	1	0.3	30	50
HIV RT	4	30	8	0.2	150	5

Table 1 shows the net selectivity observed in each step of the reaction for several polymerases. It is interesting to note that each of the polymerases shows a nearly constant selectivity of approximately 200–300 for the ground state nucleotide binding, whereas the selectivity afforded by the conformational change step (and ensuing chemistry step) contributes a widely varying selectivity. For a high-fidelity enzyme such as T7 DNA polymerase, the selectivity in the second step is 5000, leading to a net fidelity of 1.5 million. By contrast, the HIV RT shows a selectivity factor of only 50 in the conformational change step, leading to an average overall fidelity of only 13 000. Effectively, HIV RT makes at least one error each time it replicates the 9 kb viral genome, allowing the virus to rapidly evolve to evade the host immune system and any single anti-viral drug. Its low fidelity is due to the small contribution of the conformational change and/or chemistry toward the net fidelity. Moreover, because HIV RT lacks a proofreading exonuclease, once a mismatch is incorporated it is not readily removed.

Measurement of the Kinetics of Incorporation

Measurement of the kinetics of DNA polymerization is complicated by the processivity of the enzyme, defined by the tendency of the polymerase to remain bound to the DNA template/primer and to continue multiple rounds of polymerization (**Table 2**). The processivity is calculated by the rate of polymerization divided by the rate of dissociation of the E-DNA complex and is equal to the average number of bases incorporated before the complex dissociates. Although polymerization can be quite fast (50–300 s^{-1}), the rate of

dissociation is slow (typically 0.02–0.2 s^{-1}). Therefore, in the measurement of the kinetics of incorporation of a single nucleotide in the steady state with an excess of DNA and limiting enzyme, the rate that is measured is due solely to the dissociation reaction and provides no information pertaining to the nucleotide incorporation reaction, unless incorporation is slower than DNA dissociation. Therefore, steady-state rate measurements are virtually meaningless. To circumvent these difficulties, the kinetics of incorporation are measured by examining the rate of extension using single-turnover kinetic methods. A stoichiometric E-DNA complex is rapidly mixed with the correct dNTP and Mg^{2+} and then quenched by mixing with ethylenediaminetetraacetic acid to chelate metal ions needed for catalysis. The time course of extension of the DNA by one base pair is then quantified after resolution on a DNA sequencing gel.

To resolve the time dependence of extension, the reaction must be examined on the timescale of a single turnover, which usually is in the range of milliseconds. Definitive experiments require a rapid mixing device to achieve rapid mixing of small volumes. Compared to experiments using steady-state kinetic methods, single-turnover kinetic experiments may be slightly more difficult to perform, but they can be interpreted directly and often unambiguously. The nucleotide concentration dependence of the rate of the incorporation in the single-turnover reaction defines the maximum rate of incorporation, k_{pol} , which may be limited by k_2 , k_3 , or a combination of the two steps (**Figure 1**) and the ground state nucleotide dissociation constant, K_d . Because the nucleotide binding is a rapid equilibrium reaction and k_{pol} is the single, rate-limiting step in polymerization, the ratio of k_{pol}/K_d is equal to k_{cat}/K_m , the specificity constant for the reaction. Thus, this one experiment

defines the key kinetic parameter governing nucleotide selectivity and resolves it into the two steps contributing to fidelity, the ground state nucleotide dissociation constant and the rate of incorporation, k_{pol} . Most importantly, these methods provide a measurement of the equilibrium constant for the binding of the substrate to the enzyme in a complex that is poised for catalysis.

Structural Determinants of Fidelity

The structure of T7 DNA polymerase in the closed complex is shown in Figure 2. The E-DNA-dNTP closed complex was formed with the correct dNTP and a dideoxy-terminated DNA primer/template to prevent the chemical reaction from occurring. It shows the tight arrangement of the protein around the DNA and the dNTP poised for the chemical reaction to proceed. The DNA lies largely on the surface of the protein, making contacts through the phosphodiester backbone. As the DNA approaches the active site, the structure changes from standard B-DNA to an A-form DNA with a more open minor groove that allows contacts with several residues that are thought to be important for sensing mismatches in the incoming base pair as well in the primer/template. Also important to note is that the next residue in the template strand is rotated out from the active site at 90° , and protein residues stack with both the templating base and the incoming dNTP. These contacts are all thought to be important in enforcing the proper base pair geometry.

Comparison of the T7 DNA polymerase closed complex with the structures of other polymerases in the E-DNA state

reveals that there is a large conformational change in a nucleotide recognition domain involving a 45° rotation to bring key residues into contact with the dNTP at the active site. Included among these residues are positively charged lysine and arginine, amino acids that bind to the β - and γ -phosphates to facilitate catalysis, and a tyrosine that stacks with the dNTP to help align the reaction center. This conformational change step provides the most significant contribution to nucleotide selectivity by sensing the proper base pair geometry and leading to fast catalysis of the chemical reaction.

Chemistry of Catalysis

A close-up view of the reaction center is shown in Figure 3. Two tetrahedrally coordinated Mg^{2+} ions are ligated by conserved acidic residues at the active site (D475 and D654), orient the reactants, and facilitate catalysis. Metal A activates the $3'$ OH and is ligated to the non-bridging oxygen of the α -phosphate of the incoming dNTP, while metal B is ligated to nonbridging oxygens of α -, β -, and γ -phosphates and stabilizes the pyrophosphate-leaving group as the reaction proceeds. This two-metal ion mechanism appears to be common for all polymerases.

Catalysis is also critically dependent upon contacts made involving residues from the recognition domain. Positively charged residues K522, H506, and R518 contact the α -, β -, and γ -phosphates, respectively; and Y526 stacks against the incoming dNTP. These contacts are formed following the conformational change and facilitate catalysis by binding and orienting the dNTP for reaction and stabilizing the

Figure 2 Structure of T7 DNA polymerase. The structure shows the closed complex resulting from the rotation (arrow) of the recognition domain (blue) to bring the O-helix (magenta) into contact with the incoming dNTP (CPK colors). The template strand is shown in yellow, the primer strand in green, and the thioredoxin accessory protein in gray. The two metal ions at the polymerase active site and the single metal ion at the exonuclease site are shown in gold. The location of the six-residue deletion ($\Delta 6$) to create the exo-mutant is shown in red. Drawn from Protein Data Bank structure file 1T7P.

Figure 3 Two-metal ion mechanism. A close-up view of the active site shows the 3' OH of the terminal base in position to react with the incoming dNTP, bound to the two metal ions. Residues from the recognition domain contact the incoming dNTP to facilitate catalysis. Drawn from Protein Data Bank structure file 1T7P.

development of negative charge on the pyrophosphate. Thus, the structure provides a rationale for the importance of the conformational change in nucleotide selectivity and incorporation efficiency.

Selectivity of the Proofreading Exonuclease

The polymerase contains a proofreading function to efficiently remove mismatches after they are formed. This is accomplished by the polymerase recognizing it has made an error by stalling in its attempt to insert the next correct base on top of the mismatch to give time for the primer strand to flip over into the exonuclease site to have the 3'-terminal base excised. Although the exonuclease active site is 25 Å away from the polymerase site (see Figure 2), the DNA primer strand is able to flip back and forth between the two sites.

The selectivity of the exonuclease is governed by kinetic partitioning between the polymerase and exonuclease active sites, with the decision to excise being made at the polymerase site. As summarized in Figure 4, during successive correct nucleotide incorporation reactions, the polymerase continues down the DNA template, inserting bases at a rate of 300 s^{-1} . Occasionally, the DNA will dissociate from the polymerase or flip into the exonuclease site at a rate of 0.2 s^{-1} . Therefore, the cost of having a proofreading exonuclease site next to the polymerase active site is $0.2/(300 + 0.2) = 0.07\%$ of the correct nucleotides removed after correct incorporation. However, after the polymerase inserts a mismatched dNTP (occurring at an infrequent rate of 0.002 s^{-1}), the rate of incorporation of the next correct base on top of the mismatch is reduced to

Figure 4 Kinetic partitioning for exonuclease proofreading. The changes in the rates of polymerization and exonuclease removal for correct and incorrect base pairs are summarized. Correct base pairs are incorporated sequentially at a rate of 300 s^{-1} , while occasionally the DNA will dissociate (0.2 s^{-1}) or slide into the exonuclease site (0.2 s^{-1}). Mismatches are incorporated at a slow rate (0.002 s^{-1}) and extension to incorporate the next correct base is also slow (0.012 s^{-1}), but the rate of sliding into the exonuclease site is increased to 2.3 s^{-1} . This change in kinetic partitioning leads to selective removal of mismatches based upon testing for proper base pairing at the polymerase site.

0.012 s^{-1} , while the rate at which the primer flips over into the exonuclease site is increased to 2.3 s^{-1} . The probability of removing the mismatch increases to $2.3/(2.3 + 0.012) = 99.5\%$. Thus, the kinetic partitioning defining the relative probability of reaction at the polymerase and exonuclease sites is inverted when the polymerase encounters a mismatch in the primer/template.

The dynamics of the reaction provides a perfect solution to the problem of designing a proofreading function. A single-stranded primer in the exonuclease site is needed to excise the 3'-terminal base, but the DNA must be in duplex form in order to know whether the base pair is correct. According to the kinetics, the DNA spends most of the time at the polymerase site and makes only brief excursions to the exonuclease site, by melting out a single-stranded segment of the primer strand sufficient to reach the exonuclease site 25 Å away. The decision as to whether to remove a base pair is made solely at the polymerase site, based upon the ability of the enzyme to sense a mismatch in the primer template and inhibit the rate of forward reaction, thereby changing the probability of excision versus extension.

It is interesting to note that the binding of the next correct base pair is not significantly impaired with a mismatch in the primer/template; rather, the rate of the conformational change and/or the chemical reaction is reduced by the presence of a mismatch. This again is in keeping with the postulate that one purpose of the conformational change step is to test for mismatches. The proofreading selectivity demonstrates that the polymerase is capable of sensing a mismatch not only in the incoming base pair but also at the adjacent position in the primer/template, and this ability is used to increase the selectivity at each step.

Summary

DNA polymerases are remarkable machines central to the replication of all life forms on the Earth. The fidelity of different DNA polymerases varies widely in order to meet the requirements of the biology in balancing the conflicting needs for stability and adaptability. All polymerases studied in sufficient detail show a similar two-step binding mechanism to select the correct base pair using both the base pair free energy and base pair geometry.

Glossary

Cap The structure at the 5'-end of eucaryotic mRNA introduced after transcription. It results from adding a methylated G to the terminal base of the mRNA.

DNA polymerase An enzyme that synthesizes a daughter strand of DNA under direction from a DNA or an RNA template.

Hotspot A site at which the frequency of mutation (or recombination) is increased significantly.

Integrase A retroviral encoded enzyme able to insert the viral double-stranded DNA synthesized by reverse transcriptase in the nuclear genome of the infected cell.

LTR An abbreviation for long-terminal repeat, a sequence directly repeated at both ends of a retroviral DNA.

Primer A short sequence (often of RNA) that provides a free 3'-OH end at which a DNA polymerase starts synthesis of a deoxyribonucleotide chain. The primer of retroviral reverse transcriptase is a cellular transfer RNA (tRNA) molecule.

Retrovirus An RNA virus that propagates via conversion into duplex DNA.

RNase H An endoribonuclease active on the RNA moiety of DNA–RNA hybrids.

Template A polynucleotide that furnishes the instructions for the sequence of nucleotides to be added to the primer strand during DNA polymerization.

Based on our results I proposed the DNA provirus hypothesis at a meeting in 1964: the RNA of infecting Rous sarcoma virus (RSV) acts as a template for the synthesis of viral DNA, the provirus, which acts as a template for the synthesis of progeny RSV RNA. At this meeting and for the next 6 years this hypothesis was essentially ignored.

Howard Temin (Nobel Lecture 1975)

In 1964, the University of Wisconsin virologist Howard Temin proposed the DNA provirus hypothesis to explain the mechanism by which a cancer-producing virus contains only RNA infects and transforms cells. His hypothesis reversed the flow of genetic information, following what was known as the central dogma of molecular biology. Although there was a ferocious initial opposition to his hypothesis, it was widely accepted, after the discovery of reverse transcriptase (RT) in 1970. Since its discovery, RT has been associated with retroviruses. In the following years, this RNA-dependent DNA polymerase was found in eucaryotes, procaryotes, retrotransposons, hepadnaviruses, retrans, and even humans. The role of RT, essential for viral replication in all retroviruses, is to synthesize double-stranded DNA copying the retrovirus single-stranded RNA genome. This DNA is then integrated into the host cell chromosomes as a provirus. Transcription then leads to copies of the viral RNA genome, from which the virus proteins and enzymes are formed. New viral particles then bud from the membrane of the cell.

RT performs a remarkable feat, reversing the normal flow of genetic information. The polymerases synthesizing DNA and RNA in cells are very accurate and make very few mistakes. This is essential because they are the caretakers of our genetic information, and mistakes may be passed on to the offspring. RT, on the contrary, makes mistakes very often by incorporating a noncomplementary nucleotide. One might think that this low fidelity would cause severe problems to the virus. But, in fact, this high error rate turns out to be an advantage for the virus.

The errors allow the retrovirus to mutate rapidly, in order to fit new conditions and escape, for instance, the immunological response of the host or become resistant to the effect of therapeutic agents.

Discovery of Reverse Transcriptase

The publication of the presence of RT in retroviruses in 1970, by the groups of Howard Temin and David Baltimore, in the same issue of *Nature*, must be considered as a landmark in the story of biological sciences of the second half of the twentieth century. The presence of a DNA polymerase able to copy RNA into DNA (contrary to all the enzymes of this family described before which copy a DNA template into DNA) violated the so-called central dogma of molecular biology which stated that genetic information always flows from DNA to RNA to protein. It is of interest to point out that while the laboratory of Baltimore came to this observation by searching for the mechanisms used by polymerases, involved in the replication of different viruses, the findings of Temin's group came as a strong support of his earlier experiments showing that the replication of retroviruses was sensitive to inhibitors of DNA-dependent polymerases. Years later after the discovery of RT, the finding in 1983 that the cause of acquired immune deficiency syndrome (AIDS) was a retrovirus, the human immunodeficiency virus type 1 (HIV-1), and the consequent emotion provoked by the AIDS pandemics led to an explosive burst of research on this virus. It can be considered that very few organisms have provided so much information on their structure and function in such limited time as in the case of HIV-1. Most of the information on retroviral replication in these last 25 years has come from the work on this human retrovirus.

Retrovirus Genome

All retroviral genomes consist of two identical molecules of RNA, which are single-stranded, (+) sense, and have a 5'-end cap and a 3'-end poly-(A) as in the case of eucaryotic messenger RNAs (mRNAs) (Figure 1). Retroviral genomes vary in size from 8 to 11 kb. The two RNA genomic molecules are physically linked as a dimer by hydrogen bonds. The reason for the presence of two identical RNA molecules is unclear; probably they may be an advantage for the replication of the viral genome in case of damage of one of the strands. Temin showed that only one RNA is enough for viral replication. The other distinctive feature of the retroviruses concerns the fact that their genome is produced by the cellular RNA polymerase II, without the involvement of a viral-encoded polymerase. Moreover, they are the only (+)-sense RNA viruses whose genome does not serve directly as mRNA immediately after infection. Another nucleic acid, present in all viral particles, a specific transfer RNA (tRNA), is the primer required for the initiation of replication. Most, if not all, DNA polymerases require a primer carrying a free 3'-end OH from where DNA synthesis is initiated. In the case of retroviruses this primer is a cellular tRNA that is able to anneal partially to a region near the 5'-end of the RNA viral genome, the primer binding site (PBS).

Examination of the sequences of several retroviruses has shown that the PBS is complementary to the 3'-end of a given tRNA (e.g., tRNA^{Trp} in avian retroviruses, tRNA^{Pro} in murine viruses, and tRNA^{Lys3} in HIV-1). The mechanism involved in the selection of a specific tRNA is not fully understood. While the role of the viral genome has been ruled out, early results with avian retroviruses suggested that RT was involved in tRNA packaging. Very recent work seems to indicate that in the case of HIV-1, the lysine aminoacyl-tRNA synthetase may help to

encapsidate the cognate tRNA primer in the retroviral particle. The small basic nucleocapsid (NC) protein encoded in the C-terminal region of the *gag* gene plays a role in the annealing of primer tRNA to the PBS region allowing the initiation of retroviral replication. The genomic organization in all retroviruses is invariant: 5'-*gag-pol-env*-3'. However, some complex retroviruses, like HIV-1, encode several other small regulatory proteins.

Activities Associated with the Reverse Transcriptase

With the exception of some murine retroviral polymerases, most RTs are heterodimeric enzymes. The embedded retroviral-encoded protease cleaves a polyprotein precursor leading to an RT subunit that is further cleaved by the same protease. Thus, RTs are formed by two subunits where the smallest is contained in the sequence of the largest (Figure 2). Retroviral DNA synthesis is absolutely dependent on the two enzymatic activities associated with RT: a DNA polymerase that can use either RNA or DNA as a template, and a nuclease, named ribonuclease H (RNase H), that is specific for the RNA strand of RNA-DNA hybrids. In the case of avian RTs, the β subunit of the *in vivo* active enzyme also carries the retroviral integrase domain (see below). All of the enzymatic functions required to complete the series of steps involved in the generation of a retroviral DNA can be attributed to either the DNA polymerase or the RNase H of RT as described below. However, it cannot be ruled out that certain viral proteins, such as the NC protein, may increase the efficiency of reverse transcription. RT is associated to viral and cellular proteins in the so-called reverse transcription complex (RTC) that is probably closely related to the preintegration complex (PIC) described further in this article.

Figure 1 Genetic organization of retroviruses.

Figure 2 The subunit structure of different retroviral reverse transcriptases.

Reverse transcription of the retroviral genome depends on the coordination of the polymerase and RNase H activities of RT. The spatial arrangement between the two active sites of the enzyme (corresponding to about 15–18 bases in the template) contributes to the coordination of these two activities. While the 3'-OH of the primer strand is positioned close to the RT amino acid residues, important in the DNA polymerase active site, the template strand is positioned close to RT residues important for RNase H activity.

Biochemistry of Reverse Transcriptase

Mechanism of Action

The study of the mechanism of the RNA- and DNA-dependent DNA polymerase activity has led to a model involving a two-step binding mechanism. DNA polymerization catalyzed by RT is a multistep reaction, requiring the binding of the primer-template duplex and a deoxynucleoside triphosphate (dNTP) to RT prior to deoxy-nucleoside-5'-monophosphate addition to the 3' end of the primer. Kinetic experiments have established the order of binding of the substrates. The primer-template duplex binds prior to binding of the dNTP substrate to form the catalytically competent ternary complex (Figure 3). The rate-limiting step for nucleotide incorporation prior to dissociation of the enzyme is a conformational change. Following pyrophosphate liberation, the elongated product is released. Small changes in the rates and equilibrium constants have been observed for RNA- versus DNA-dependent DNA synthesis. All these mechanisms have been derived from pre-steady-state or steady-state kinetic assays using short primer-templates and do not always reflect the true nature of reverse transcription, although they are necessary in determining the kinetics and affinity of substrate binding to RT.

Processivity

The elongation phase of DNA synthesis by DNA polymerases may be processive or distributive. A processive DNA polymerase is able to synthesize long DNA stretches without dissociation of the enzyme from the primer-template duplex while a distributive polymerase dissociates easily after incorporation of few nucleotides. RT is considered to be poorly processive as compared with replicative DNA polymerases. However, a higher processivity of RT may be observed when copying specific regions of the viral genome or in the presence of some viral proteins.

Fidelity

All RTs show poor fidelity when compared with host DNA polymerases in *in vitro* systems. The lack of a proofreading function as well as the enzyme ability to extend mismatched primer termini probably explains much of this high error rate. The tendency of RT to switch templates, paired with its ability to extend mismatches by incorporating wrong nucleotides,

may be a significant source of replication errors. The error rates of various RTs estimated in different types of assays can be significantly affected by altering the parameters of the reaction. The error rate is quite dependent on sequence context and hot spots, where errors occur frequently, may differ according to the particular RT used in the assay. In addition, error rates may be different on RNA and DNA templates. As a consequence, it is not possible to define the error rate as a single number. These studies, taken together, do suggest that the overall error rate is high: about one per genome in a reverse transcription cycle. Cellular factors may alter error rates and some studies suggest that somewhat lower error rates occur *in vivo*. However, the *in vitro* data lead to the generally accepted impression that the average retroviral DNA genome differs from its parent by at least one mutation and provide the evidence for the existence of retroviral quasi-species.

Replication Errors *In Vivo* and the Emergence of Antiviral Resistance

The rates at which mutations accumulate in retroviral and in the host genomes are very different since the viral genomes are found to evolve at rates perhaps a million fold higher than the nuclear host genomes. The lack of RT fidelity and the accumulation of nonlethal mutations are closely related to the emergence of resistance toward antiviral therapeutic agents. This effect is especially dramatic in the case of HIV-1, the causal agent of AIDS. After short times of treatment, viral quasi-species appear with mutations in the viral target proteins (the most used targets against HIV-1 are RT and protease). The introduction of the so-called combination therapy against AIDS has greatly improved the possibility to keep the seropositive patients for several years with a low or undetectable viral charge. The combination of several anti-proteases and anti-RTs makes possible that, if a given mutation leads to the apparition of resistance against a specific drug, the other antivirals are still effective giving time to replace the one to which the target enzyme has become resistant.

Inhibitors of Reverse Transcriptase

Emphasis in the search of RT inhibitors has been obviously focused on the HIV-1 enzyme but some of the inhibitors developed against this agent may be useful in arresting human or animal retroviruses involved in other pathologies. Inhibitors of HIV-1 RT were the first therapeutic agents described against AIDS. Later appeared the protease inhibitors, and currently, inactivating agents against other viral targets (viral entry, integrase, and fusion) are used in AIDS patients resistant to the usual treatments. As mentioned above, the combined use of anti-proteases and anti-RTs has led to a great improvement in the control of HIV-1 proliferation in AIDS patients. Two main families of HIV-1 RT inhibitors are used against AIDS, the nucleoside analogs inhibitors of RT (NRTI) and the non-nucleoside inhibitors of RT (NNRTI). The first ones are

Figure 3 The kinetics of the reverse transcription reaction.

recognized and incorporated by RT in the newly synthesized DNA but as they lack, or have, a modified group in the 3' position of the ribose they cannot be linked to the following dNTP precursor and thus they act as chain terminators. To be active *in vivo*, the putative NRTI, which are active against all retroviral RTs, must be triphosphorylated by cellular kinases. The first NRTI described was azidothymidine or zidovudine (AZT), but currently more than a dozen of these inhibitors have been approved by the US Food and Drug Administration (FDA) and are used in clinics. It is important to point out that the resistance to NRTIs may appear by either mutations in the RT leading to the nonrecognition of the NRTI or a more recently identified RT activity consisting in the pyrophosphorolysis and further elimination of the terminator nucleotide. A second family, the NNRTIs, is specific of the HIV-1 RT since they inhibit the viral polymerase after binding to a hydrophobic region of this enzyme. They do not have a typical nucleoside structure, but belong to a variety of different chemical families of compounds, and in contrast to NRTIs they do not need to be metabolized inside the cell to display their antiviral effect.

Recombination

Since retroviruses ordinarily carry two identical or nearly identical RNAs, the genetic consequences of using only one versus portions of both of the RNAs to template DNA synthesis are usually the same. However, under certain conditions, two genetically distinct RNAs can be encapsidated. Portions of each template can be used to generate a single DNA, producing a recombinant virus. Recombination does occur in virions produced by a single cell that has been co-infected by two different viruses demonstrating that recombination requires co-packaging of two viral genomes into the same particle. During reverse transcription in such heterozygous virion particles, the DNA product can be generated containing portions of each of the two genomic sequences in one molecule.

The Role of RT in Reverse Transcription

Reverse transcription catalyzed by RT begins when the viral particle enters the cytoplasm of a target cell. DNA synthesis using the RNA retroviral genome as template takes place in the cytoplasm leading to a linear double-stranded DNA (dsDNA), co-linear with the viral RNA template, the proviral DNA. However, proviral DNA contains terminal duplications known as the long terminal repeats (LTRs) that are not present in viral RNA.

The following scheme is widely accepted to reflect the process of retroviral DNA synthesis catalyzed by RT (Figure 4):

1. Minus-strand DNA synthesis starts from the 3' end of a tRNA partially annealed to PBS in genomic RNA. Minus-strand DNA synthesis proceeds until the 5'-end of genomic RNA is reached, generating a short DNA intermediate termed minus-strand strong-stop DNA (–sssDNA). Since the PBS is near the 5'-end of viral RNA, the length of this strong-stop DNA is about 100–150 nucleotides.
2. Following RNase H-mediated degradation of the RNA strand of the RNA(–sssDNA) duplex, the first strand

Figure 4 Reverse transcription steps.

transfer involves the annealing of the –sssDNA to the complementary 3'-end of a viral genomic RNA. This transfer is allowed by the presence of identical sequences known as the repeated (R) sequences, present at the 5'- and 3'-ends of the RNA genome. The 3'-end of –sssDNA is copied from the R sequences at the 5'-end of the viral genome and therefore contains sequences complementary to R. After the RNA template has been removed, the –sssDNA can anneal to the R sequences at the 3'-end of the RNA genome. The annealing reaction related to the first strand transfer appears to be facilitated by the NC protein.

3. Once the –sssDNA has been transferred to the 3' R region on viral RNA, minus-strand DNA synthesis may start again, followed by RNase H digestion of the template strand.
4. RNase H degradation is not complete since some hybrid regions seem to be more resistant to the nuclease. The RNA genome contains a short polypurine tract (PPT) that is relatively resistant to RNase H degradation. A defined RNA segment derived from the PPT primes plus-strand DNA synthesis. Plus-strand synthesis is halted after a portion of the primer tRNA is reverse-transcribed, leading to a DNA called plus-strand strong-stop DNA (+sssDNA). Some retroviruses generate more than one plus-strand primers from the RNA genome.

5. RNase H removes the primer tRNA, exposing sequences in +sssDNA that are complementary to sequences at or near the 3' end of plus-strand DNA.
6. Annealing of the complementary PBS segments in +sssDNA and minus-strand DNA constitutes the second strand transfer.
7. Plus- and minus-strand syntheses are then completed by RT, with the plus and minus strands of DNA each serving as a template for the synthesis of the other strand.

Ribonuclease H Activity of RT

The functions of retroviral RNase H embedded in RT are essential during DNA synthesis. Several steps of reverse transcription require this activity as seen in the retrotranscription scheme (Figure 4). Kinetic studies have shown that RT lacking RNase H activity is incapable of supporting DNA strand transfer. This has been confirmed in a variety of retroviral systems in culture. RNase H activity requires the presence of divalent cations, four conserved amino acids (one glutamic and three aspartic residues) being close to the Mg^{2+} site.

As two obligatory strand transfer events occur in the production of proviral DNA, it would be of considerable interest to identify molecules able to interfere with these steps. Inhibitors of DNA translocation and RNase H activity could provide new lead compounds for treating HIV-1 infection. Unfortunately, the *in vitro* inhibitors of retroviral RNase H studied until now have proved to be inactive *ex vivo* or *in vivo* because of minimal cell uptake or/and cytotoxicity.

The best-studied retroviral RNase H is that of HIV-1 associated with the p66 subunit of RT. Contrary to some other retrovirus, the RNase H domain of HIV-1 RT expressed as an isolated recombinant protein is inactive due to the importance for this activity of some amino acid residues present in the RT DNA polymerase domain. When the HIV-1 RNase H domain was purified and mixed with a separately expressed and purified fragment containing the DNA polymerase domain of HIV-1 RT, RNase H activity was restored. The three-dimensional (3D) structure of the isolated HIV-1 RNase H domain was solved to a resolution of 2.4 Å and compared with the *Escherichia coli* RNase H structure. Several conserved amino acids are present in both enzymes. Despite limited sequence homology, the structures of the RNase H of HIV-1 RT and the RNase H of *E. coli* are remarkably similar. During RNase H cleavage concomitant with DNA elongation, the 3'-terminus template-primer complex spans the polymerase and RNase H domains, with 18–19 nucleotide base pairs between the primer terminus and the cleavage site. This represents the distance between the polymerase and RNase H active sites of HIV-1 RT determined by biochemical and structural studies. No clear data is available on the specificity of the cleavage mechanism of RNA by the viral enzyme.

Integration and Retroviral Replication

As proposed by Temin since the early 1960s, retrovirus replication is performed via a DNA intermediate, the proviral DNA that is synthesized by the RT in the cytoplasm. Integrase (IN), the third retroviral encoded enzyme in addition to RT and

protease, is involved in the integration of the proviral DNA in the nuclear DNA of the infected cell. Integration of the proviral DNA synthesized by RT into the host genome has the advantages of increasing the long-term stability of the viral information inserted in the chromosomes and also takes profit of the cellular enzymes involved in gene expression. Thus, once integrated, the proviral DNA is recognized by the host RNA polymerase II for the efficient transcription of viral DNA into new copies of the viral genome and mRNAs. Transcription of the proviral DNA is facilitated by the viral-encoded Tat protein. These mRNAs are then translated into the viral proteins.

IN catalyzes two reactions, the first one takes place in the cytoplasm and concerns the cleavage of two terminal residues of the proviral DNA and the second step operates in the nucleus and involves the integration of the provirus in the nuclear DNA (Figure 5).

Both the central catalytic domain and C-terminal domains have been shown to bind both viral and cellular DNA. Studies of early steps of IN attachment to viral DNA showed that the specificity of IN for DNA is linked to its oligomerization state. Interestingly, this mechanism is also observed with other proteins sharing high structural analogies with retroviral IN and RNase H such as eukaryotic transposases (*mariner*) and the maize Mu transposase. As expected, the structure of HIV-1 IN has attracted special attention. At the present time, no crystal structure data of the entire HIV-1 IN or IN bound to its DNA substrates exists but biochemical and structural studies show that IN functions as a dimer or a tetramer. Very recently, the group of Cherepanov described a crystal structure of full-length integrase from the prototype foamy virus IN in complex with its cognate DNA. The structure shows the organization of the DNA-IN complex comprising a tetrameric integrase tightly associated with a pair of viral DNA ends. Foamy viruses (FVs) also known as spumavirus are complex retroviruses that are widespread in many species. Infection of natural hosts by FV leads to a lifelong persistent infection, without any evidence of pathology. While FV are ubiquitous in all nonhuman primates, they are only acquired as rare zoonotic infections in humans.

The 3D structure of the catalytic domain of HIV-1 integrase shows a remarkable similarity with the structure of the isolated HIV-1 and *E. coli* RNase H as well as with other enzymes belonging to the polynucleotide phosphorylase family (Figure 6). The latter led to the description of inhibitors able to affect simultaneously these two retroviral targets.

The transfer of the viral DNA and the IN into the nucleus takes place in a multimeric PIC composed of viral and cellular encoded proteins. The exact composition and the mechanism of nuclear entry of the PIC is still controversial but in addition to the IN and the proviral DNA, some consensus exists on the presence in the PIC of the viral proteins RT, viral protein R (VPR), NC, and cellular factors playing a role in the recognition of the chromosomal integration locus (Ini1, LEDGF/p75). Concerning the trafficking mechanism of the PIC from the cytosol to the nucleus, it has been proposed that the cytoskeleton and the centrosome may play a role in this process.

The importance of the retroviral IN in the HIV-1 replication cycle has fostered the search of specific inhibitors of this enzyme (Figure 7). Among the pharmacophores identified as integrase inhibitors by the pharmaceutical companies Merck and Shionogi were the β -hydroxyketo group, diketo group, or a

Figure 5 Scheme of the two steps of integration.

carboxylate group (DKA). From these studies, a reaction in the presence of Mg^{2+} was shown to be the most stringent condition with respect to strand transfer inhibition. The first HIV integrase inhibitor, Raltegravir, was approved by the FDA on October 2007 for use in antiretroviral treatment experienced adult patients with viral resistance against other anti-HIV agents.

Role of Reverse Transcriptase in Modern Biology

Nowadays, it is known that RT not only is present in animal retroviruses but also plays a crucial role in DNA replication of procaryotic and eucaryotic cells, in the replication of some plant and animal DNA viruses, as well as in the function of several classes of transposable elements. As mentioned in the remarkable book *Retroviruses*:

it should be remembered that RT has had a critical role in the development of modern biology. The ability to convert RNA into DNA has been as important to molecular biologists as it has been to retrovirologists. It is worth taking a moment to reflect on how much more difficult it would have been to solve the puzzles posed by the organization and expression of genes in higher eucaryotes if RT did not exist.

Glossary

Autonomously replicating sequence (ARS) A DNA sequence that imparts origin activity to extrachromosomal elements in the presence of appropriate replication proteins, and whose activity is sensitive to genetic alterations.

Cdc Cell division cycle protein. A large number of Cdc genes have been identified in eukaryotes that affect various stages in cell division. Cdc6 is the name used in the budding yeast, *Saccharomyces cerevisiae*; Cdc18 is the name used in the fission yeast, *Schizosaccharomyces pombe*. The nomenclature for budding yeast proteins is generally applied to other organisms.

Cdk Cyclin-dependent protein kinase. This phosphorylates specific amino acids in proteins, but only when associated with a cyclin protein.

Cdt1 A protein encoded by Cdc10-dependent transcript 1 in *S. pombe*. Cdt1 is the same as RLF-B in *Xenopus laevis*.

DNA replication origin The DNA site where replication begins; also called an origin of bidirectional replication.

Mcm Minichromosome maintenance proteins. These were identified as genes required to maintain plasmids in *S. cerevisiae*. At least seven of these proteins are involved in DNA replication.

Origin recognition complex (ORC) Six different proteins that bind to DNA replication origins and thereby initiate assembly of a pre-replication complex.

Pre-replication complex (pre-RC) Fourteen different proteins consisting of ORC, Cdc6, Cdt1, and Mcm(2–7) that form a complex with chromatin during G1 phase of the cell cycle and that become the site where DNA replication begins during S phase.

Replicator A DNA sequence that imparts origin activity when translocated to other chromosomal regions, and whose activity is sensitive to genetic alterations.

Eukaryotic cells replicate their DNA with remarkable precision during the course of growth and division. Each genomic region should be replicated once and only once per cell cycle to avoid genomic instability. To assure such an accuracy of genome duplication, eukaryotes have evolved a mechanism for the initiation of DNA replication that involves multiple origins of replication (*ori*) along the chromosomal DNA. DNA replication in eukaryotes is a highly conserved process that begins with the binding of the six-subunit origin recognition complex (ORC) to the origins of DNA replication. ORC binds to origin sites in an ATP-dependent manner and helps in recruiting and in the assembly of additional initiation factors (Cdc6, Cdt1 and mini-chromosome maintenance proteins (MCM) 2–7 helicase complex) to form pre-replicative complex (pre-RC), thus licensing origin for further replication activity. Before the S phase, the combined action of cyclin-dependent kinases (CDK) and Dbf4-dependent kinases (DDK) results in the loading of additional replication proteins to form the pre-initiation complex (pre-IC). DNA synthesis is initiated after the recruitment of DNA polymerase complexes (polymerase α -primase and polymerase ϵ).

Structure and Diversity of Eukaryotic Origins

Replicon Model

The basis of our current views on replication initiation stems from replicon model, proposed by Francois Jacob and Sydney Brenner in 1963. In this model, a replicon, defined as a DNA molecule capable of autonomous replication, is characterized by two functional components – initiator and replicator. A *trans*-acting

initiator protein binds to a specific sequence, DNA *cis*-element called replicator. Upon binding, initiator is transformed into replication-competent form which is followed by a replication initiation at the replicator site.

DNA replication starts with the separation of DNA strands (DNA unwinding) resulting in a formation of replication forks moving in opposite directions. Due to the antiparallel nature of the DNA duplex, DNA synthesis occurs continuously on one strand (leading strand) and discontinuously on the other (lagging strand). As DNA polymerases can travel along their templates only in one direction (5′–3′), the DNA synthesis on a lagging strand results in short DNA fragments (Okazaki fragments) which are joined together by DNA ligase.

Replication Origins in Prokaryotes, Viruses, and Lower Eukaryotes

Replicon model was first solidly proven in prokaryotic organisms. In *Escherichia coli*, initiator protein DnaA binds specifically to the 250-bp AT-rich replicator sequence *oriC*, resulting in a local ATP-dependent DNA unwinding and replicative DNA helicase (DnaB) loading. This is followed by the assembly of replication fork components, including DNA polymerases, and a replication initiation.

Viral origins contain short species-specific sequences. These sequences are bound by a single virus-encoded protein (such as SV40 T antigen). The binding is highly sequence-specific; even mild alterations of the viral origin strongly affect replication. Unlike most eukaryotic origins, viral origins can initiate replication several times during the same cell cycle. Viral origins are functionally independent from neighboring sequences.

This represents another difference from eukaryotic initiation sites in which origin activity may be strongly influenced by the context of a surrounding DNA.

The most well-studied and characterized eukaryotic replication origins are found in the genomes of yeast cells. In budding yeast, *Saccharomyces cerevisiae* sites of replication initiation were originally identified in a screen for genomic regions supporting replication of extrachromosomal plasmids which carry them. These regions were termed autonomously replicating sequences (ARS) and were shown to have a significant sequence similarity with each other. A typical ARS has size of approximately 100 bp and consists of 11-bp ARS-consensus sequence (ACS or A element) and another less-conserved 10- to 15-bp element (B element) essential for origin function. Mutations in these two elements affect binding of ORC to the origin. At the same time, many studies suggest that additional factors and epigenetic parameters, such as nucleosome positioning, are also important in defining of origin selection and function.

Unlike budding yeast, the origins in other eukaryotic species are significantly less strictly defined. Even in fission yeast, *Schizosaccharomyces pombe* origins are much larger (500–1000 bp) and are not conservative in sequence, except for being AT-rich. The latter feature is apparently important for ORC binding, as *S. pombe* Orc4 subunit contains multiple AT-rich sequence-binding motifs (AT-hooks) at the N-terminal part of the protein. Reduction in AT-content of origins results in delayed initiation, thus illustrating connection between sequence composition and functional characteristics of origin in *S. pombe*.

Metazoan Origins

Difference from budding yeast origin structure is even more obvious in metazoan species where origins are large and do not exhibit any sequence conservation; no sequence elements analogous to yeast ARS were found. Situation is even more complicated by a large size and complexity of the genomes in higher eukaryotes, and consequently, by a significant number of replicons and replication initiation sites (Figure 1). For example,

Figure 1 Replication origins in prokaryotes and eukaryotes. Bacterial chromosome contains one origin which initiates single replication fork. Multiple potential origins are found on eukaryotic chromosomes. Activation of these origins is coregulated with replication fork progression rate; if forks slow down, additional origins are activated.

an estimated 30 000 replication origins may function at different times in human cells. Distribution and localization of origins change during development in metazoans, which further obscures the study and an understanding of origin-defining factors in these species. Such flexibility of DNA replication in metazoans is well exemplified by the crucial change in this process during the development of insects and amphibians. In *Drosophila melanogaster* early embryos and *Xenopus laevis* fertilized eggs, DNA replication is extremely rapid, taking only 10–30 min for complete replication of the whole genome due to large number of functioning origins spaced as close as 4–7 kb. In these conditions, frequent initiation of replication employs practically all available origins. Later in development, origin distribution significantly changes, with the initiation occurring selectively on a fraction of all origins, and time needed for genome replication also increases up to 8–10 h.

Some of the most characterized origins are found in *D. melanogaster*. These origins control an amplification of two clusters of chorion genes in somatic follicle cells that surround developing oocyte. At a specific stage of oogenesis, these two genomic regions on the third and X chromosome are amplified up to 60-fold by supporting extra rounds of DNA replication. This process is followed by high expression of the chorion genes, required for the successful formation of the eggshell. Two *cis*-regulatory elements important for the amplification were identified within the chorion gene cluster: the 400 bp amplification control element 3 (ACE3) and ~1 kb ori β . It was shown that *Drosophila* ORC localizes to the chorion amplification gene cluster in follicle cells, and that ACE3 and ori β are sufficient to drive this localization. ORC also binds these sequence elements *in vitro*, however, in DNA-binding assays, *Drosophila* ORC shows at best sixfold preference for the chorion locus origin DNA compared to random DNA fragments. This suggests that origin determination in metazoan relies on the mechanisms other than simple initiator–replicator sequence recognition.

Many metazoan origins were mapped by different methods in mammalian cells. They can be roughly subdivided into two groups. Origins of one group localize to relatively confined locations on chromosomes. One example of this type of origins is human β -globin locus. This locus includes five genes that encode β subunit of hemoglobin. DNA replication initiation occurs within several kb region located in the intergenic space between δ - and β -globin genes. Removal of this initiation region abolishes origin activity. Under these conditions, β -globin locus is passively replicated from outside origin. Initiation region itself contains two independent nonoverlapping replicators, and each of them is sufficient to induce replication in ectopic sites upon transfer. Combination of asymmetric purine–pyrimidine sequence and several AT-rich stretches is required for replication initiation activity of these replicators.

The second type of higher eukaryotes origins is characterized by large extended initiation zones, tens of kilobases in size. Initiation in these origins occurs infrequently at multiple sites distributed across the entire region. One of the better studied origins of this kind is Chinese hamster ovary dihydrofolate reductase (*DHFR*) locus, a 240-kb chromosomal domain amplified in methotrexate-resistant CHO cell line. In this locus, replication initiation events are mapped across the whole 55-kb intergenic region. The initiation of DNA replication is sensitive

to mutations in specific sequences surrounding the initiation zone. For example, the deletion of the *DHFR* promoter allows initiation to occur within the *DHFR* gene, which does not normally initiate replication. Removal of specific sequences at the 3' end of the *DHFR* gene, causing *DHFR* transcripts to extend to the intergenic region, confines initiation to the far 3' end of the locus.

Importantly, no consensus origin sequence was found among the metazoan initiation sites. *In vitro* DNA-binding assays demonstrate that metazoan ORC preferentially binds to sequences with higher AT-content, though it is unable to differentiate between naturally occurring origin sequences derived from known initiation sites and artificial AT-rich DNA fragments. Thus, origin specification in higher eukaryotes apparently involves other factors rather than simple recognition of replicator sequence by initiator.

Specification and Selection of Eukaryotic Origins

Mechanisms or Origin Specification

Several mechanisms have been described which participate in targeting ORC to the specific sites on a DNA. First, ORC itself has a DNA-binding ability. The binding of ORC to DNA occurs with high specificity in budding yeast, however, in metazoan species, ORC does not have a strong preference for binding to a particular DNA sequence but still favors AT-rich DNA. Second, other replication initiation proteins, such as Cdc6, could enhance ORC interaction with origin sequences. Third, other factors, such as transcription factors or chromosomal proteins, which interact specifically with DNA, could be involved in recruiting ORC to specific sites in the genome. Fourth, characteristics and state of chromatin structure in specific regions of the genome could restrict the areas where ORC can function. Finally, certain specific conditions such as nucleotide pool level or DNA methylation may also influence ORC binding and assembly of the pre-RC.

DNA topology may be one of the factors determining a choice of the binding site by ORC. In *in vitro* DNA-binding experiments, *Drosophila* ORC demonstrates significant preference for negatively supercoiled DNAs, binding to them with 30-fold higher affinity as compared to linear or relaxed DNA fragments. Such topological sensitivity of ORC binding is closely related to another important factor – a chromatin structure of the binding site. There are several examples of changes in origin usage as a result of alterations in local chromatin structure. In yeast, mutations in histone deacetylase (HDAC) Sir2 facilitate initiation events, rescuing replication mutants involved in pre-RC assembly. In *Xenopus* and humans, HBO1, a histone acetyltransferase (HAT) directly interacts with the components of pre-RC and is required for MCM loading onto chromatin. Chromatin acetylation was also shown to be critical for chorion gene cluster amplification in *Drosophila* follicle cells.

Influence of chromatin structure on the replication initiation is not restricted to histone acetylation events. In *Xenopus* system, DNA methylation state was shown to affect initiation. Origin activity is repressed by highly methylated state which interferes with the ORC binding. However, if a low-methylated region is created on such DNA, ORC binding is detected, and replication initiation occurs. Also, DNA methylation was

shown to determine replication start location, either directly or indirectly, in mammalian cells.

Transcription is known to induce a negative supercoiling which facilitates DNA unwinding required for the replication initiation. This idea is supported by the data that, replication initiation frequency in fission yeast genome is twice as high in the intergenic regions of divergent transcription, compared to the ones of convergent transcription. Also, formation of active transcription complex can specify replication origin on the plasmid DNA in *Xenopus* extracts.

Preferential localization of replication origins to the actively transcribed regions, also suggests that an open chromatin state associated with these regions is favorable for the replication initiation. Many yeast origins are known to be located in the proximity of promoters. Moreover, direct interactions between ORC and transcription factors E2F1, Rb and Myb complex important for chorion gene expression, are described in *Drosophila*. Mutations in these genes affect localization of ORC and a function of chorion-cluster amplification origin. Another example of tight transcription–replication association comes from studies in human cells, where Epstein-Barr virus (EBV) transcription factor EBNA1 (EBV-coded nuclear antigen 1) participates in recruitment of ORC to the viral replication origin, *oriP*. These results could partially explain why all attempts to identify consensus sequence of higher eukaryotes origin have failed; various transcription factors could impart both developmental and DNA sequence specificity to each particular origin.

Replication factors such as Cdc6 can also participate in the origin specification. In budding yeast, interaction between ORC and Cdc6 is facilitated by origin DNA and reduces dissociation rate of ORC from origin. In metazoan species, Cdc6–ORC interaction might also enhance DNA binding by ORC. It is possible, that Cdc6 and transcription factors act in combination to specify the interactions between ORC and DNA.

Origin Plasticity

Important characteristic of the origin selection process is its dynamical regulation. This feature is illustrated by the origin plasticity phenomenon, described by J. Herbert Taylor in 1977. Under the conditions of thymidine starvation of Chinese hamster ovary cells, when rate of replication fork progression is decreased, total replication rate is compensated by the increase in the number and frequency of replication initiation events; cells with slower fork movement activate additional origins. On the other hand, acceleration of fork progression results in a decrease in the number of active origins. Thus, replication fork movement rate and distances between active origins are coordinately regulated (Figure 1).

The number of genomic sites with assembled pre-RC is higher than the number of the sites of actual replication initiation. Pre-RC sites are formed in excess; possibly, to supply a pool of additional origins which can be utilized when needed. This mechanism protects genome from being under-replicated, since the regions which would be out of reach for stalled or slowed replication forks started from usually active origins, would still be replicated due to the activity of the local dormant origins.

The mechanism of dormant origins activation could be mainly stochastic. In this model, dormant origins are repressed by passing replication forks which originated from preferred,

normal origins. However, under conditions of the replication stress, dormant origins become unrepressed since the replication forks do not reach them. Another model stipulates that stalled replication fork induces conformational changes in the surrounding chromatin and facilitates replication initiation from less preferred dormant origins. In any case, dormant origin activation would be triggered by the changes in replication fork progression.

Methods to Study DNA Replication

Current understanding of eukaryotic origin structure, selection, and DNA replication in general was achieved by the employment of a broad array of *in vitro* and *in vivo* methods. The most important of them include chromatin immunoprecipitation followed by analysis on microarrays (ChIP-Chip) or direct high-throughput sequencing (ChIP-seq) where ORC or other components of pre-RC are cross-linked to the DNA, isolated by immunoprecipitation and associated DNA is identified. DNA footprinting as well as assays based on identification of early replication intermediates, such as nascent DNA strand assay and 2D gel analysis, are also important *in vivo* approaches. Important quantitative parameters of replication, such as origin densities in the genome and rates of replication fork progression, are assessed using DNA fiber-based approaches where chromosomes are pulse-labeled with modified nucleotide precursors and newly synthesized DNA is visualized by immunofluorescence. Cell-free systems that allow studies of DNA replication *in vitro* are described for humans, *Xenopus* and *Drosophila* and can be used for functional dissection of the processes and factors involved in the initiation of DNA replication.

Origin Recognition Complex as the Core of Replication Initiation Machinery

ORC Discovery, Conservation, and Structure

The identification of the ORC in *S. cerevisiae* was an important advance in understanding eukaryotic DNA replication. It was identified by Stephen Bell and Bruce Stillman in 1992 as a factor that specifically bound to the yeast ARSs. Yeast ORC is composed of six tightly associated protein subunits, ranging from 104 kDa (Orc1) to 50 kDa (Orc6). Since its original discovery, evidence has steadily accumulated that ORC plays a central role in the initiation of DNA replication and recruitment of other essential replication factors to the Ori.

ORC has been conserved throughout eukaryotic evolution. ORC subunits and/or complete ORC complexes have been identified in *S. pombe* and various metazoans, including *D. melanogaster*, *X. laevis*, and humans. This conservation of ORC, as well as numerous other factors required for DNA replication, strongly suggests that there must be common mechanisms for the initiation of DNA replication in all eukaryotes, despite dramatic differences in the structure of eukaryotic origins of DNA replication and an absence of obvious conserved sequences among them.

ORC proteins also share homology with another component of pre-RC—Cdc6. This protein is well conserved among eukaryotes and may be a paralog of Orc1. Moreover, Orc1 can be more related to Cdc6 than to other ORC subunits. The structural

data indicate that ORC and Cdc6 may form a ring-like structure around the DNA reminiscent of MCM helicase ring.

Subunits 1–5 of ORC as well as Cdc6 contain conserved Walker A and B ATP-binding domains within the AAA+ fold. These features are characteristic of the proteins which form ring-shaped complexes and bind DNA in the central channel of the ring. The N-terminus of Orc1 contains bromo-adjacent homology (BAH) domain which is important for protein–protein interaction and provides a structural basis for ORC functions in heterochromatin. Orc6, on the other hand, does not share any of the structural features of Orc1–5 and has its own characteristic domains; unique conserved Orc6 protein fold domain at the N-terminus and the coil-coiled motif at the C-terminal part found in metazoan species. This coil-coiled region is important for cytokinetic functions of Orc6.

ORC Functions in Pre-RC Formation

Binding of ORC to DNA specifies sites where initiation of replication will occur, and this process is ATP-dependent. Experimental data indicate that ATP binding by ORC, but not the ATP hydrolysis, is important for DNA binding by the ORC. The coordination of DNA and ATP binding by ORC probably involves allosteric interactions among the subunits. It seems that ORC can exist in alternative conformational states induced by stable interaction of ORC with ATP and origin DNA. In humans, it was shown that ATP is also required for maintenance of ORC integrity and serves as a structural cofactor for ORC.

Even though ORC is bound at specific chromosomal regions containing origins of replication in both differentiated *Drosophila* and human somatic cells *in vivo*, little is known about how ORC complex finds these sequences. Several mechanisms which target ORC to the specific sites on the DNA were proposed. Among those are DNA topology and modifications, chromatin structure, transcription, transcription and replication factors, and nucleotide pool levels. These mechanisms of ORC targeting to specific DNA sites are addressed in more detail above (see section Specification and Selection of Eukaryotic Origins).

Although ORC plays a central role in the initiation of DNA replication in all eukaryotes, the interaction of this protein complex with replication origins in other species differs in some respects from that observed in *S. cerevisiae*. Fission yeast *S. pombe* has larger and more complex origins than *S. cerevisiae*. These origins contain multiple AT-rich elements important for its function. The *S. pombe* Orc4 subunit contains an N-terminal domain that binds to origin DNA even in the absence of other ORC subunits. This domain contains nine copies of the AT hook motif found in a number of DNA-binding proteins. The AT hook motif is known to bind to the minor groove of AT tracts. The N-terminal domain of *S. pombe* Orc4 may function to tether the ORC complex to origins of DNA replication. This interaction is independent of ATP. However, the tethered complex may also make ATP-dependent contacts with additional sites in the origin to nucleate formation of the initiation complex.

ATP-dependent ORC binding to DNA provides basis for the sequential recruitment of a number of additional replication factors which together form pre-RC (Figure 2). The recruitment of Cdc6 and Cdt1 occurs first, followed by the repeated

Figure 2 Assembly of the pre-RC. Binding of ORC to the replication origins marks the beginning of pre-RC assembly. On the next step, Cdc6, and then Cdt1, join origin-bound ORC. These proteins together facilitate initial association of MCM2-7 helicase with chromatin. Hydrolysis of ORC- and Cdc6-bound ATP results in loading of MCM2-7 onto DNA.

loading Mcm2-7, a hexameric-helicase complex responsible for unwinding parental DNA strands. ORC, together with Cdc6 and Cdt1, emerges as a part of a helicase loading machinery that facilitates the assembly of multiple Mcm2-7 complexes which play a crucial role in origin function. Specifically, a coordinated ATPase activity of ORC and Cdc6 facilitates tighter loading of initial MCM2-7 helicase onto the origin DNA along with recruitment and binding of additional MCM2-7 complexes.

MCM2-7 loading concludes formation of the pre-RC as shown in **Figure 2**. At this point, origin is licensed for further activity and ready to proceed to pre-IC assembly. As cells continue through the G₁ phase toward S phase transition, additional replication factors are recruited to the origin including CDKs and DDKs, Cdc45, Mcm10, GINS complex, the three eukaryotic DNA polymerases, and the eukaryotic ssDNA-binding protein, RPA. In the absence of ORC, the assembly of the pre-RC fails in both cells and cell-free systems, even so ORC by itself has only been shown to interact directly with a small subset of these factors. In these events, ORC not only serves as a landing pad but also actively participates in the assembly of pre-RC at the origins. Interestingly, the artificial recruitment of eukaryotic replication initiation factors, such as ORC and/or Cdc6, to a DNA can create a functional origin of replication.

Regulation of ORC Activity

Regulation of replication initiation and pre-RC formation is an important mechanism of preventing re-replication and avoiding genomic instability. As a critical component of these processes, ORC becomes the target of several regulatory pathways. In multicellular eukaryotes, one or more ORC subunits dissociate from the complex soon after the formation of pre-RC is complete. For example, in *Drosophila*, Orc1 subunit is selectively ubiquitinated by APC/Fzr and degraded. In mammalian cells, Orc1 is ubiquitinated through the SCF(Skp2) system and in some cases degraded, however, this subsequent degradation is not mandatory, suggesting several mechanisms of

mammalian Orc1 regulation in different cell lines/types. Cdk activities have both negative and positive roles in the initiation of DNA replication and cell-cycle progression. Numerous studies have shown the role of Cdk in the prevention of re-replication through direct inactivation of pre-RC proteins. The molecular consequences of ORC phosphorylation that inhibit pre-RC formation are not completely elucidated. It is likely, that modification directly inhibits association between ORC and other components of the pre-RC. Overall, this multi-level, cell-cycle-dependent regulation of ORC activity is a crucial step in preventing re-replication during single cell-cycle progression. ORC does not merely select the sites for assembly of pre-RC; it is also an important component of multiple cellular pathways that determines when pre-RCs are assembled. In all eukaryotic organisms, ORC subunits undergo cell-cycle-dependent modifications involving phosphorylation and ubiquitination that repress ORC activities during S, G₁, and M phases. ORC activity is restored after a completion of mitosis.

Nonreplicative Functions of ORC

Many studies indicate that the functions of ORC extend beyond DNA replication. The first discovered nonreplication function for ORC was its participation in the establishment of transcriptionally silent chromatin domains at the budding yeast silent mating type loci (HMR and HML) through the interaction with the silent chromatin protein Sir1. ORC's function in the establishment of transcriptionally repressed regions appears to be a conserved feature, as both *Drosophila* and mammalian ORC interact with HP1, a well-known modifier of position effect variegation. Mutations in the *Drosophila* Orc2 gene suppress position effect variegation and alter the localization of Hp1. siRNA knockdown of Orc2 in human cells results in delocalization of HP1. Human ORC also interacts with the histone acetyl transferase, HBO1 suggesting that histone acetylation around origins is an active process in which chromatin is remodeled by replication initiators.

Another nonreplication function of ORC is related to mitotic events in the chromosomes. Different ORC subunits in yeast, *Drosophila*, and human cells are involved in events such as sister chromatid cohesion, chromosome condensation and chromatid segregation in the mitosis, and mutations in ORC subunits cause defects in these processes.

In both *Drosophila* and human cells, the smallest subunit of ORC, Orc6, has been implicated in coordinating cytokinesis with pre-RC formation and chromosome segregation, a role that it performs independently of the rest of the complex. Orc6 had been found at the cell membranes and cytokinetic furrow in *Drosophila* and mammalian cells. RNAi/siRNA knockdown of Orc6 in either *Drosophila* or human cells results in reduction of DNA synthesis, and also in the prominent appearance of cells that have completed mitosis without cytokinesis (multi-nucleate cells), a phenotype that is not seen following knockdown of other ORC subunits. In *Drosophila*, Orc6 interacts and colocalizes with the Pnut protein, a member of the septin complex which is required for cytokinesis and other processes that involve spatial organization of the cell cortex. Experimental data suggest that Orc6 may be involved in the regulation of septin complex activities such as guanosine triphosphate hydrolysis and filament formation, and thus control dynamic

cytoskeleton events driven by septins. Also, involvement of ORC component into cytokinesis may be important for coordination between replication and subsequent mitotic events.

Concluding Remarks

Recent years of research brought significant progress in our understanding of replication–initiation events. Though basic principles of this process are universal, species-specific differences in certain components and steps of replication–initiation can be significant. This is further complicated by the plastic and adjustable character of replication. Such flexibility exists on multiple levels, from connection between replication fork progression rate and density of active origin in the genome, to diverse global patterns of replication in various tissues and on several developmental stages.

Many significant questions related to the understanding of replication–initiation mechanisms and their modifications in different species are still open. Among the most important of them are the exact criteria of origin specification, selection, and regulation. What determines whether a particular locus would be an origin and whether this origin would be active or dormant? How exactly is the activation of dormant origins achieved? What determines the timing of origin firing? The role of ORC in other than DNA replication cell functions, such as heterochromatin formation and transcriptional silencing, chromosome condensation and cohesion, and cytokinesis is an additional example of connections between different regulators of the cell cycle. In-depth study of ORC and pre-RC components functions which span beyond replication, can potentially clarify important global regulatory mechanisms connecting different seemingly isolated pathways, such as replication and chromosomal M phase events, cytokinesis, and transcriptional silencing.

Glossary

DNA helicase An enzyme that unwinds the two strands of a DNA duplex.

DNA ligase An enzyme that covalently joins two DNA strands together.

DNA polymerase An enzyme that synthesizes DNA by incorporating nucleotides at the 3' end of the new strand that are complementary to the nucleotides on the strand serving as the template.

Lagging strand The strand at the replication fork that is synthesized discontinuously by making shorter fragments that are sealed together by DNA ligase.

Leading strand The strand at the replication fork that is synthesized continuously as one long strand.

Primase An enzyme that synthesizes the short RNA primers to begin the discontinuous fragments on the lagging strand of a replication fork.

Two Strands of the DNA Duplex Are Copied by Different Mechanisms

DNA usually exists as a double-stranded structure, with both strands coiled together to form the characteristic double helix. The pairing of bases in DNA through hydrogen bonding means that the information contained within each strand is redundant allowing for both strands of parent DNA to serve as templates for the synthesis of new DNA. Thus, one of the strands of each daughter DNA molecule is newly synthesized and the other is passed on unchanged from the parent DNA molecule. DNA strands have directionality; the different ends of a single strand are referred to as the 3' end or the 5' end indicating which carbon atom in deoxyribose is attached to the next phosphate in the chain. In duplex DNA, the parent strands are antiparallel or oriented in opposite directions (Figure 1). This directionality has consequences for DNA synthesis, because DNA polymerase can only synthesize DNA in one direction by adding nucleotides to the 3' end of a DNA strand. The parent DNA strand oriented 3'–5' relative to the movement of the replication fork may serve as a template for the continuous synthesis of one daughter DNA strand and is called the leading-strand template. However, the other parent DNA strand is oriented 5'–3', so that the polymerase copying this strand moves away from the replication fork and is called the lagging-strand template. DNA replication on the lagging strand is accomplished by a discontinuous mechanism in which the polymerase makes short fragments that begin near the fork and extend for 1000–3000 bases (Figure 1). These fragments, known as 'Okazaki fragments' after their discoverer, are then joined together by DNA ligase to form the second daughter DNA strand. To allow for the rapid and coordinated synthesis of the leading and lagging strands, Bruce Alberts proposed that the lagging strand folds into a loop, bringing the two polymerases together (Figure 2). This has been called the trombone replication model because the expansion of the loop, as each Okazaki fragment is synthesized, resembles the slide of a trombone.

Proteins Required for DNA Replication

Much of our present understanding of bacterial DNA replication comes from the characterization of the replication system

of *Escherichia coli* and the simpler systems of *E. coli* bacteriophage T4 and T7. The fundamental components that constitute a functional replication fork in bacteriophage faithfully represent more complex systems. The types of proteins necessary for DNA replication are shown in Figure 2, and the specific proteins for each of these three systems are given in Table 1.

DNA Polymerase Holoenzymes

Replicative DNA polymerases are distinguished by their rapid and accurate DNA synthesis. The *E. coli* polymerase III, T4 polymerase gp43, and T7 polymerase gp5 are capable of extending the 3' end of an existing nucleotide chain by several hundred nucleotides every second. Replicative DNA polymerases are generally extremely accurate making only one misincorporation for every 10^7 nucleotides (nt) added. To decrease the error frequency even further, many replicative polymerases, including these three, possess a 3'–5' exonuclease proofreading activity able to remove the 3' nucleotide if a mismatch is accidentally incorporated. These polymerases alone are not processive and produce short DNA product strands each time they bind to the DNA template. To increase the processivity of these polymerases so that thousands of nucleotides can be incorporated during a single DNA-binding event, the *E. coli* and T4 polymerases interact with a circular-clamp protein that surrounds the duplex DNA and slides as the polymerase moves forward. These clamp proteins need to be loaded on the DNA by multisubunit complexes of proteins known as 'clamp loaders' using the energy from adenosine triphosphate (ATP) hydrolysis. Isolation of the *E. coli* Pol III holoenzyme yields a complex containing two polymerase cores for the leading and lagging strands, two clamps, and a single multisubunit clamp loader. The clamp loader (γ -complex) travels with the polymerases which are linked through the C-terminal domain of the two τ -subunits. The T4 proteins are less tightly associated with the holoenzyme consisting of only the polymerase and clamp; the clamp loader departs the complex once the holoenzyme is assembled. There is evidence that the two T4 polymerases at the fork interact with each other at least transiently. The T7 DNA replication system does not include a clamp or clamp loader; rather, the T7 DNA

Figure 1 Schematic diagram of leading- and lagging-strand DNA synthesis at a replication fork. The parental DNA strands are antiparallel and the new DNA strands lengthen by addition of nucleotides to the 3' end causing the leading strand to be synthesized continuously, whereas the lagging strand is synthesized in short fragments known as Okazaki fragments.

polymerase is isolated as a complex with *E. coli* thioredoxin, which serves the same purpose as a clamp and increases the processivity of the polymerase.

Primosomes

A DNA polymerase can only extend an existing DNA strand paired with a template strand; it cannot begin the synthesis of a new strand. Therefore, primase proteins are required to make very short RNA chains, called 'primers', in order to initiate each Okazaki fragment for the DNA polymerase to extend on the lagging strand. The length, typically 4–12 nt, and sequences of the primers are different in each of these systems. In the bacterial replication systems, there is a close physical and functional relationship between the primase and helicase proteins. The bacterial replicative helicases are ring-shaped hexamers that surround the lagging-strand template moving 5'–3' on that strand to unwind the duplex DNA by a reaction that requires hydrolysis of nucleotide triphosphates. The DnaC helicase-loading protein promotes loading of the *E. coli* DnaB helicase by opening the preformed helicase hexamer allowing the ssDNA to bind inside. By contrast,

Figure 2 Cycle of steps for lagging-strand DNA synthesis at a bacterial replication fork. Depicted is the trombone model of DNA replication with the lagging strand folded to bring the leading- and lagging-strand polymerases together. (a) Extension of a lagging-strand fragment that began with primer P2. (b) The size of the loop increases as the nascent fragment is extended and the helicase continues to unwind duplex DNA. The primer P1 from the previous Okazaki fragment is hydrolyzed. (c) The polymerase is released after it completes the fragment frequently leaving behind the clamp. The nick between the fragments is sealed by DNA ligase. A new primer P3 is synthesized for the next Okazaki fragment. (d) Polymerase is transferred to the new primer P3 to begin elongation of the next fragment. The figure shows the reactions that must be completed in each cycle, but the order and timing of some of the steps, such as ligation of adjacent fragments relative to polymerase transfer, has not been established.

Table 1 Protein composition of the *E. coli* and bacteriophage T4 and T7 DNA replication systems

	<i>E. coli</i>	Phage T4	Phage T7
Polymerase holoenzyme			
Polymerase	Polymerase core (α , ϵ , θ)	gp43	gp5 + <i>E. coli</i> thioredoxin
Clamp	β (dimer)	gp45 (trimer)	
Clamp loader	γ -complex (γ , τ , τ , δ , δ' , χ , ψ)	gp44/62 complex	
Primosome

Ligase	<i>E. coli</i> DNA ligase	T4 DNA ligase	T7 DNA ligase

^aT7 gp4 protein catalyzes both helicase and primase reactions.

the T4 helicase-loading protein binds to the DNA fork and facilitates the assembly of the gp41 helicase subunits into a hexamer surrounding the lagging-strand template. The T7 primase and helicase activities are both catalyzed by gp4, which forms a protein hexamer of stacked rings of primase and helicase domains. There is no helicase-loader protein in the T7 replication system; rather, the ssDNA binds first to a primase site and then the ring opens to allow the DNA to reach the center of the helicase ring.

Single-Stranded DNA-Binding Proteins

The single-stranded DNA of the lagging strand created by the action of the helicase is covered by tightly binding single-stranded DNA-binding proteins. In *E. coli*, this protein is a tetramer known as single-stranded-binding (SSB) protein, which the ssDNA winds itself around, while in T4 and T7, these proteins are monomers known as gp32 and gp2.5, respectively. In general, SSB proteins protect the ssDNA from nucleases until it can be replicated, prevent the formation of secondary structure in the ssDNA that can inhibit polymerases, and bind specifically to several other replication proteins, including polymerases, primases, and gp59 in the T4 system, to modulate their activities.

5'–3' Nucleases and DNA Ligases

To complete the synthesis of the lagging strand, the RNA primers of the Okazaki fragments must be removed and the fragments joined. The RNA primers are removed by 5'–3' nuclease proteins that are capable of degrading both RNA: DNA and DNA:DNA duplexes. Once the RNA primer is removed and any gap between fragments filled in by a DNA polymerase, the fragments are joined by DNA ligase.

Synthesis at DNA Replication Forks

Leading-Strand Synthesis

The continuous leading-strand DNA synthesis at the replication fork begins with an RNA primer that is made by an RNA polymerase. The leading-strand polymerase holoenzyme loads on the 3' end of the RNA primer and couples with a helicase bound to the opposite lagging-strand template. The rates of synthesis by the polymerase and duplex unwinding by the helicase are much greater when these proteins work together at a replication fork, than when these reactions occur separately. The polymerase holoenzyme and helicase are connected directly to each other in the T7 system and through the τ -subunit of the clamp loader in the *E. coli* system. The physical coupling between the polymerase holoenzyme and helicase in T4 is currently not well understood. DNA synthesis on the leading strand is extremely processive and, in principle, a single polymerase can remain bound to complete the synthesis of the chromosome of the three systems described here. However, evidence now shows that bacterial replication forks frequently stall before completing the chromosome replication and must be restarted.

Lagging-Strand Synthesis

Synthesis of the lagging strand at the replication fork begins with an RNA primer that is made by a primase. However, because the lagging strand is made in short Okazaki fragments, several RNA primers are necessary in a repeating cycle of primer initiation, elongation by DNA polymerase, and ligation to seal the fragments (Figure 2). Okazaki fragments are 1000–3000 bases in length and replication is proceeding at 400–1000 bases s^{-1} , so the cycle of reactions on the lagging strand must be completed in a few seconds. Reactions required to prime the next fragment, elongate the present fragment, and remove primers from the previous fragments can occur simultaneously allowing the lagging strand cycle to be completed rapidly.

Beginning in the elongation stage of this cycle, the lagging-strand polymerase holoenzyme is synthesizing an Okazaki fragment that began with the primer labeled P2 (Figure 2(a)). At the same time, the helicase surrounding the lagging-strand template at the fork is unwinding the duplex ahead of the leading-strand polymerase holoenzyme. The ssDNA being generated by the helicase along with the ssDNA remaining to be replicated ahead of the lagging-strand polymerase holoenzyme is coated with SSB proteins.

As the lagging strand loop continues to grow due to the activities of the helicase and lagging-strand polymerase holoenzyme, the 5'–3' nuclease is removing the RNA primer (P1) and a small amount of adjacent DNA from the previous fragment (Figure 2(b)). The removal of this DNA first added to the primer may increase the accuracy of replication.

When the lagging-strand polymerase holoenzyme completes the nascent fragment, creating a nick, the clamp releases the polymerase and stays behind on the DNA (Figure 2(c)). In *E. coli*, this release of the polymerase core from the β -clamp is facilitated by the C-terminal domain of the τ -subunit of the clamp loader acting as an unloader. There is no evidence that a clamp loader is needed to disengage the clamp and polymerase in the T4 system. If the polymerase fails to be released at

the nick, it can continue to synthesize DNA displacing the 5' end of the downstream fragment forming a flap. However, all of the prokaryotic 5' nucleases involved in primer removal also have flap endonuclease activities able to remove these displaced strands. The nicks that are formed between adjacent fragments are sealed by DNA ligase.

When the synthesis of the nascent fragment is complete, primase, associated with the helicase at the fork, makes the RNA primer (P3) that will be used to start the next fragment (**Figure 2(c)**). A new clamp is loaded on to the primer in the *E. coli* and T4 systems by the clamp loader. The *E. coli* clamp loader is bound to the two polymerases as well as the helicase at the fork, while the clamp is recruited from solution. Dilution experiments suggest that both the T4 clamp and clamp loader must be provided from solution for each cycle of lagging strand synthesis. Sometimes, the primase makes a primer before the lagging-strand polymerase holoenzyme finishes the previous Okazaki fragment. This acts as a signal that causes the lagging-strand polymerase to be released prematurely leaving a gap between fragments that must ultimately be repaired by loading another polymerase.

Finally, the lagging-strand polymerase is transferred to the clamp-loaded new primer (P3) to begin synthesis of the next fragment (**Figure 2(d)**). In the case of T7, the DNA-binding domain of the primase binds the new primer and transfers it directly to the lagging-strand polymerase. The same lagging-strand polymerase is recycled from one Okazaki fragment to the next being held at the replication fork by interactions with the clamp loader in *E. coli*, the leading-strand polymerase in T4, or the helicase in T7.

Coordination of Leading- and Lagging-Strand Synthesis

The cycle of reactions for lagging-strand synthesis must be carefully coordinated with each other as well as with the reactions on the leading strand. Experiments using synthetic templates, which allow for the separate detection of leading- and lagging-strand synthesis, have demonstrated that the leading-strand synthesis is stopped either when a chain terminator was added or by the absence of rNTPs for primer synthesis to block lagging-strand synthesis, indicating a close interaction between the polymerases on the two strands. With the complexity of the multiple steps involved in primer and Okazaki fragment synthesis on the lagging strand and the relatively straightforward continuous incorporation of nucleotides on the leading strand, two models have been proposed to maintain this coordination. In the first model, the leading-strand synthesis temporarily stops or pauses to allow additional time for primer synthesis and polymerase recycling to occur on the lagging strand, after which the coordinated synthesis on both the leading and lagging strands continues. Some evidence suggests that the T7 system may operate this way. In the second model, the leading-strand polymerase holoenzyme never pauses; rather, the lagging-strand polymerase is occasionally signaled to recycle prematurely before completing the nascent fragment, thereby catching up to the leading-strand holoenzyme. Evidence

suggests that in the *E. coli* and T4 systems, the leading-strand synthesis never stops and that lagging-strand polymerase recycling occurs prematurely up to 50% of the time.

DNA Replication within the Cell

DNA replication is initiated at particular points within the DNA known as 'origins'. The *oriC* origin in *E. coli* contains an A-T rich sequence recognized by the replication initiator protein, DnaA. DnaA subsequently recruits other proteins beginning a series of reactions that result in the separation of the DNA strands at the origin, forming a bubble with two replication forks at either end. In bacteria, which have a single origin of replication on their circular chromosome, the bidirectional DNA synthesis eventually creates a theta structure because the DNA resembles the Greek letter theta, θ . Termination of replication occurs when the two replication forks meet each other on the opposite side of the parental chromosome. *E. coli* regulate this process through the use of the Tus protein and termination sequences that allow replication forks to pass through in only one direction, but not the other. Thus, the two replication forks are constrained to always meet within the termination region of the chromosome. Regulation of DNA replication in *E. coli* is achieved through several mechanisms, including the ratio of ATP to adenosine diphosphate (ADP) and the levels of DnaA within the cell, as well as the hemimethylation and sequestering of *oriC*. DNA synthesis results in hemimethylated DNA recognized by the SeqA protein. SeqA binds the hemimethylated DNA and sequesters the origin sequence preventing newly replicated origins from immediately initiating another round of DNA replication before cell division.

Glossary

Bidirectional DNA replication DNA synthesis that originates at the origin of replication and results in the formation of two replication complexes leading to two replication forks that move in opposite directions.

DNA polymerase Enzyme that utilizes a primed single-stranded DNA (ssDNA) template to synthesize the complementary strand.

Helicase Enzymes that use the energy derived from hydrolysis of nucleoside triphosphates to break the hydrogen bonds that hold the duplex DNA together.

Primase Enzyme that synthesizes small RNA chains *de novo* on ssDNA resulting in RNA–DNA hybrids, which are used as primers for DNA polymerases.

Sliding clamp Ring-shaped protein that encircles duplex DNA and binds to the DNA polymerase, endowing it with high processivity.

Introduction

All organisms must replicate their chromosomal DNA in order to propagate their genetic information. During the S phase of the cell cycle, DNA replication duplicates chromosomes into two identical copies that segregate to daughter cells during mitosis. Chromosomal DNA replication begins at regions of the chromosomes called origins of replication and can be divided into three phases: initiation, elongation, and termination. In the initiation stage, an origin recognition protein (ORP) binds the origin of replication to form the initial replication bubble and recruits additional initiation factors to the origin. Next, the helicase is recruited and assembled on the DNA. The single-stranded DNA (ssDNA) exposed behind the helicase is coated with ssDNA-binding protein (SSB). Primase, the polymerase, and the rest of the replication machinery are associated with the replication bubble to form two replication forks and to initiate bidirectional DNA synthesis (the elongation phase). During termination, replication forks collide and are resolved, and the resulting daughter DNA molecules are completed and separated. A number of proteins and complexes that participate in replication fork progression are described in the article.

Due to the antiparallel nature of the DNA and the unidirectionality of the polymerase, one strand of the chromosome is synthesized continuously (the leading strand) while the other is copied discontinuously (the lagging strand) as a series of Okazaki fragments (Figure 1). It is believed that at the replication fork, the two polymerases responsible for replicating the leading and lagging strand are associated (either directly or indirectly via other molecules). Thus, the replication of the two strands is coupled.

Minichromosome Maintenance Complex

Minichromosome maintenance (MCM) is a family of six proteins (Mcm2–7, molecular masses of 101, 91, 97, 82, 93, and 81 kDa, respectively) with highly conserved amino acid

sequences between the six different polypeptides. The family was first identified in a screen for proteins required for the maintenance of minichromosomes in yeast. All six proteins have been identified in all eukarya. Based on genetic and biochemical studies, the MCM complex is presumed to be the helicase responsible for the separation of duplex DNA during chromosomal replication. All MCM proteins are essential for cell viability. They are needed for the initiation phase as well as for replication fork progression. In addition to the MCM heterohexamer, *in vivo* and *in vitro* studies have revealed the presence of several additional MCM complexes composed of different combinations of MCM proteins. Biochemical studies with these various complexes from different organisms showed that *in vitro* a dimeric complex of the Mcm4,6,7 heterotrimer contained 3'–5' DNA helicase activity, ssDNA and double-stranded DNA (dsDNA) binding, DNA-dependent ATPase activity, and could translocate along ssDNA and dsDNA and unwind a DNA–RNA hybrid when translocating on the DNA strand. It was also found that the heterohexamer of Mcm2–7 possesses 3'–5' DNA helicase activity *in vitro*, but only in the presence of accessory factors Cdc45 and the GINS complex [referred to as the CMG (Cdc45–MCM–GINS) complex]. It is believed that the CMG complex is the active helicase at the replication fork. The 3'–5' direction of translocation on DNA by the MCM proteins suggests that the helicase moves along the leading strand.

Replication Protein A

Replication protein A (RPA) is the eukaryotic ssDNA-binding protein. It is a heterotrimeric complex of proteins with molecular masses of 14, 32, and 70 kDa; these essential proteins have been found in all eukarya studied. SSBs are essential components of all replication systems. The protein coats the ssDNA exposed behind the helicase, protecting the DNA from attack by nucleases and chemical modification. In addition, RPA stimulates the activity of DNA polymerases by removing

Figure 1 A schematic representation of the proteins at the eukaryotic replication fork. Although it is not shown in the figure, it is thought that all proteins shown interact with each other but the factor responsible for the interaction has not been identified.

secondary structures that interfere with polymerase movement, creating a uniform substrate for polymerase activity. RPA was shown to play an instrumental role in the coordination of DNA synthesis on the lagging strand and to interact with a large number of cellular factors needed for DNA metabolism.

DNA Polymerase α /Primase Complex

DNA polymerases are incapable of initiating DNA synthesis *de novo* and require DNA primases, which synthesize short RNA primers on template DNA that are subsequently extended by the polymerase. In eukarya, DNA primase is part of a four-subunit complex, the Pol α /primase complex, containing subunits with molecular masses of 180, 68, 58, and 48 kDa. Two of the subunits, p48 and p58, are required for primase activity, with p48 serving as the catalytic unit. Primase synthesizes short RNA primers (8–12 nucleotides (nt)), which are then elongated by polymerase α (Pol α) to ~30 nt, forming pre-Okazaki fragments. These RNA–DNA hybrid molecules are recognized by the polymerase accessory complex, replication factor C (RFC), to initiate processive DNA synthesis by the replicative polymerase. On the lagging strand, Pol α /primase activity is required at the initiation of each Okazaki fragment.

Polymerase Accessory Proteins

The processivity of DNA polymerases is low. This means that only a few nucleotides are incorporated into the newly synthesized DNA before the polymerase dissociates from the substrate. Processivity is conferred by a ring-shaped protein, referred to as the DNA polymerase sliding clamp (also called DNA polymerase processivity factor), which encircles duplex DNA and acts to tether the polymerase catalytic unit to the

primed template for processive DNA synthesis. The eukaryotic sliding clamp is the proliferating cell nuclear antigen (PCNA). PCNA, as well as the other sliding clamps, cannot assemble itself around the DNA, but must be loaded onto DNA by a protein complex, known as the clamp loader (also called polymerase accessory complex), which in eukarya is RFC. RFC recognizes the 3' end of the single-strand/duplex (primer–template) junction of the pre-Okazaki fragment and utilizes ATP hydrolysis to assemble PCNA around the primer. PCNA encircles the primer DNA and then binds the DNA polymerase, allowing rapid and processive DNA synthesis. Upon completion of an Okazaki fragment, the polymerase dissociates, leaving the clamp assembled around the duplex DNA.

Proliferating Cell Nuclear Antigen

PCNA, the eukaryotic sliding clamp, is a ring-shaped homotrimer of a 29-kDa protein, which is assembled on the leading strand by RFC and interacts with DNA Pol ϵ , the leading strand polymerase, to initiate processive DNA synthesis. On the lagging strand, PCNA must be loaded on each primer. Upon assembly around the primer of the pre-Okazaki fragment by RFC, PCNA associates with DNA Pol δ to initiate processive DNA synthesis. Upon completion of an Okazaki fragment, PCNA disengages from the polymerase and is left on the duplex DNA. The PCNA molecules left on replicated DNA play diverse roles in postreplication DNA metabolic processes by interacting with and stimulating a large number of enzymes. Examples of enzymes stimulated by PCNA include Fen1 and DNA ligase, needed for Okazaki fragment maturation. PCNA is a target for cell-cycle regulators. A number of proteins that inhibit DNA synthesis were shown to operate via interaction with PCNA, preventing its association with the polymerase.

Replication Factor C

RFC, the eukaryotic clamp loader, is a five-subunit complex of 140-, 40-, 38-, 37-, and 36-kDa proteins (for Rfc1–5, respectively). All five subunits are essential for cell viability and all belong to the AAA+family of ATPases. In addition to the conserved domains found in all members of this family, the large subunit (Rfc1) shares homology with prokaryotic DNA ligases at its N-terminal region. RFC recognizes the 3' end of the pre-Okazaki fragment and utilizes ATP hydrolysis to assemble PCNA around the duplex DNA. It was shown that the interaction between RFC and RPA plays a role in the switch that removes Pol α /primase from DNA, allowing the loading of PCNA. In addition to its role as a clamp loader, *in vitro* studies suggest that RFC also functions as a clamp unloader, that is, it removes PCNA from DNA.

Polymerase δ and Polymerase ϵ

Both Pol δ and Pol ϵ are found in all eukarya and are essential polymerases required for chromosomal DNA replication. Pol δ is a heterotetramer of proteins with molecular masses of 125-, 66-, 50-, and 12-kDa proteins, while Pol ϵ is comprised of proteins of 261, 59, 17, and 12 kDa. Both polymerases were shown to be monomeric in solution. Following the assembly of PCNA at the primer, Pol δ and Pol ϵ associate with PCNA to initiate rapid and processive DNA synthesis. *In vivo* genetic studies and *in vitro* biochemical characterization have suggested that Pol ϵ and Pol δ act on different DNA strands. These studies suggested that Pol ϵ is the leading strand polymerase while Pol δ is the lagging strand enzyme.

Topoisomerases

During replication, DNA is supercoiled in front of and behind the polymerase. Positive supercoils are produced in front of the replication fork, while negative supercoils result behind it. Topoisomerases prevent excessive supercoiling and regulate the level of supercoiling within the DNA molecule. These enzymes are essential for replication fork progression. Topoisomerases introduce transient breaks in the phosphodiester backbone of the DNA and allow supercoils to be added or removed.

Additional Proteins

The replication of eukaryotic chromosomes is a very complex and highly coordinated process. To date, dozens of proteins have been shown to participate in the replication of eukaryotic chromosomes. However, the replication fork continues to be studied, and recent work suggests that more proteins may be a part of the fork, such as the GINS complex, MCM10, and Cdc45. The roles, if any, of these enzymes at the fork remain to be elucidated.

Glossary

DNA polymerase III holoenzyme The replicative DNA polymerase of *E. coli*.

DNA replication The process of duplication of DNA.

DnaA box A 9-bp DNA sequence motif recognized by DnaA protein.

DnaA protein DnaA is the initiator of DNA replication, recognizing DNA sequence motifs named the DnaA box, the I-site, and the τ -site in the chromosomal replication origin.

DnaB protein Composed of six identical subunits, DnaB helicase is a ring-shaped protein with a central cavity through which one of the two strands of DNA passes as the helicase unwinds the parental duplex DNA.

DnaC protein DnaC forms a complex with DnaB helicase to inhibit its activity as a DNA helicase and ATPase.

Formation of the DnaB–DnaC complex is required for DnaA to load DnaB at *oriC*.

I-site A sequence within *oriC* bound by DnaA complexed to ATP.

oriC The *Escherichia coli* chromosomal replication origin where DNA replication starts.

Primase This enzyme forms primers that are extended by DNA polymerase III holoenzyme during DNA replication.

SSB SSB is an acronym for single-stranded DNA-binding protein.

τ -site A sequence within *oriC* recognized by DnaA complexed to ATP.

In free-living organisms, including *Escherichia coli*, DNA replication starts at replication origins. *E. coli* contains a single replication origin (*oriC*), which serves as the site for assembly of the replisome, a multi-protein molecular machine that duplicates the circular duplex genome. Replisome assembly is a highly regulated event that is strictly coordinated with the cell cycle.

The *E. coli* Replication Origin, *oriC*

The biochemical mechanism of DNA replication of the *E. coli* chromosome has been extensively studied. At *oriC*, DnaA directs the formation of two replisomes for bidirectional fork movement. As an adenine–nucleotide-binding protein, DnaA specifically recognizes DNA sequences in *oriC* and then loads DnaB helicase bound to its partner, DnaC. The focus of this article is on the biochemical mechanism of initiation. Recent excellent reviews offer different perspectives of this process and its regulation, and are listed in the section Further Reading.

DNA Sequence Motifs in *oriC*

E. coli oriC has been studied by a variety of approaches. A number of DNA sequence motifs that are functionally important have been identified (Figure 1). One is an AT-rich region near the left border that carries three 13-mer motifs. In the absence of magnesium ion *in vitro*, this region has a natural tendency to unwind and is also called the DNA unwinding element (DUE). In the presence of magnesium ion, DnaA is required for unwinding as described in more detail later. Between this region and the right border are discrete binding sites recognized by DnaA and other proteins. Three types of binding sites for DnaA have been identified. One is called the

DnaA or R box, whose consensus sequence is TTA/TTNCACA. Each of these boxes is designated as R1 through R5 (or M) to denote their positions within *oriC*. A domain (domain IV, see Table 1) near the C-terminus of DnaA recognizes these DnaA boxes. Other sites in *oriC* are named I- and τ -sites.

The affinity of DnaA for the DnaA boxes varies, which apparently reflects the influence of differences in both their sequence composition and flanking sequences. Their order of affinities is $R4 \geq R1 > R2 > R3 \approx R5$. As DnaA binds to adenosine triphosphate (ATP) and adenosine diphosphate (ADP), either nucleotide-bound form binds with comparable affinity to R4 and R1. For the other DnaA boxes, DNase I footprinting with a polymerase chain reaction (PCR)-amplified DNA containing *oriC* showed that DnaA–ATP binds more avidly than DnaA–ADP to R2, R3, and R5, but this difference was not observed with dimethyl sulfate as the cleaving reagent in the footprinting of DnaA bound to a supercoiled plasmid carrying *oriC*. As an explanation for the disparity in results, the difference may arise from the effect of DNA topology (supercoiled compared with a linear DNA). A second possibility is that the inclusion of poly (dI–dC) and poly (dA–dT) in the DNase I experiments and their omission in the experiments with dimethyl sulfate leads to this difference. In comparison, DnaA complexed to ATP binds with lower affinity to sites named I- and τ -sites. At present, it is not known if domain IV of DnaA interacts directly with the I- and τ -sites. However, because the I-sites differ from the R box consensus only at 3–4 bases, it is likely that domain IV of DnaA recognizes both of these types of DNA sequences. As *oriC* contains 11 GATC sites recognized by DNA adenine methylase (Dam) and several overlap the τ 1, τ 2, I2, and I3 sites, the methylated state of these sites in the *oriC*-containing plasmid compared with the nonmethylated PCR-amplified DNA may influence binding affinity.

Figure 1 DNA sequence motifs in *E. coli oriC*. Three 13-mers (green boxes) are located near the left border. The black arrowheads denote the orientation of the DnaA boxes named R1, R2, R3, R4, and R5 (or M). The I- and τ -sites bound by DnaA complexed to ATP, and binding sites for IHF (purple box) and Fis (red box) are also shown.

Table 1 Functional domains of DnaA^a

Domain	Region of DnaA	Function
I	1–90	DnaA oligomerization Interaction with DnaB–DnaC, HU, DiaA, or Dps
II	91–130	Linker connecting domains I and III
III	131–347	ATP binding and ATP hydrolysis DnaA oligomerization (Box VII) Interaction with DnaB (residues 130–148)
IV	348–467	DNA binding Interaction with acidic phospholipids (residues 372–381)

^aDomain I acts in the recruitment of the DnaB–DnaC complex, in DnaA oligomerization, and in the interaction of DnaA with HU, DiaA or Dps. Distinct regions within domain I act in DnaA oligomerization and in the recruitment of the DnaB–DnaC complex. Domain II may function as a flexible linker, and participate in loading the DnaB–DnaC complex. Domain III contains the Sensor I, II (Box VIII), and Box VII motifs of the AAA⁺ protein family, and functions in ATP binding, ATP hydrolysis, and in DnaA oligomerization. A region (residues 130–148) within domain III also interacts with DnaB. Domain IV functions to recognize the DnaA box motif. A region within domain IV (residues 372–381) is implicated in membrane binding.

Of interest, the R4 box can be scrambled or the right half of *oriC* can be removed entirely from the chromosomal locus without loss of viability. However, initiation is severely asynchronous compared with the synchronous initiation at the respective origins in wild-type cells harboring replicating chromosomes. Evidently, sequences in this region that include the R4 box are needed for the temporal regulation of initiation. The importance of sequences in the right-half of *oriC* recognized by DnaA complements several lines of evidence showing that the ordered assembly of DnaA is essential for the coordination of initiation with the cell cycle.

Binding Sites for Other Proteins

Sites for the binding of integration host factor (IHF) and factor for inversion stimulation (Fis) are located between R1 and R5, and R2 and R3, respectively (Figure 1). Both nucleoid-associated proteins bend DNA upon binding. *In vivo*, footprinting studies of *oriC* minichromosomes in synchronous cultures revealed that the R3 box was occupied at the time of initiation. At other times, the Fis site was protected, but R3 was not. These results suggest that the exchange of Fis with DnaA at the

respective sites is essential for initiation to occur at the proper time in the bacterial cell cycle. Mutation of either binding site disrupted *oriC* function when carried in a plasmid, suggesting that the binding of these proteins to these sites is important for initiation. In support, Fis and IHF mutants, although viable, initiate asynchronously and fail to maintain *oriC*-dependent plasmids, but the IHF mutant requires an additional *polA* mutation to elicit the latter defect. The conundrum is that mutation of these binding sites in the bacterial chromosome does not inhibit *oriC* function *in vivo*, and plasmids with mutations in the Fis or IHF binding sites are active *in vitro*.

Replisome Assembly Is a Stepwise Process

The biochemical mechanism of initiation at *oriC* can be separated into discrete steps. Studies of these events rely in part on an *in vitro* DNA replication system that requires a supercoiled plasmid containing *oriC* and other purified components, including DnaA, DnaB, DnaC, single-stranded DNA-binding protein (SSB), HU, primase DNA polymerase III holoenzyme, and DNA gyrase. By the following criteria, this system recapitulates the *in vivo* process. First, the *in vitro* system absolutely requires the *oriC* sequence; mutations that abolish *oriC* function *in vivo* when carried in a plasmid also inactivate *oriC* in the *in vitro* system. Second, replication forks that propagate from *oriC* move bidirectionally as they do *in vivo*. Third, the *in vitro* system requires many of the same gene products that are required in living cells. This system coupled with other biochemical approaches has led a mechanistic view of the function of each required protein.

The DnaA–*oriC* Complex

As an adenine-nucleotide-binding protein, DnaA contains the amino acid sequence motifs shared by the AAA⁺ family of proteins. These motifs are the Walker A and B boxes, which respectively function in nucleotide binding and in coordinating magnesium chelated to the phosphates of the nucleotide, and sensor I, II, and box VII motifs that are considered to both promote and coordinate ATP hydrolysis with a conformational change. As predicted in the initiator titration model, initiation occurs at a particular cell mass when the abundance of DnaA reaches the level necessary for initiation. Thus, DnaA binds to the high-affinity sites early in the bacterial cell cycle. As ATP is more abundant than ADP *in vivo*, DnaA that is newly synthesized more likely binds ATP over ADP. As DnaA–ATP accumulates, it binds to the low-affinity sites, which include the R3 box and the I- and τ -sites, forming the DnaA–*oriC* complex. In support, *in vivo* footprinting experiments in synchronized cells reveal that DnaA is bound to R1, R4, and R2 throughout the cell cycle, and that R3 becomes protected at the time of initiation. When this study was performed, the other low-affinity sites had not been discovered.

In vivo and *in vitro* evidence indicates that formation of the DnaA–*oriC* complex requires an interaction between and/or among DnaA molecules. Two regions within DnaA are required. Based on studies of a mutant DnaA carrying an alanine substitution for tryptophan 6 (W6A), one region appears to be a hydrophobic surface near the N-terminus.

This mutant protein is defective in an assay (see later) that measures the assembly of DnaA at *oriC* in a supercoiled plasmid followed by the recruitment of DnaB complexed to DnaC. Other studies that rely on footprinting methods showed that this mutant DnaA fails to protect the I- and τ -sites within *oriC*. Together, these results suggest that the hydrophobic surface functions in DnaA oligomerization to stabilize the interaction between and/or among DnaA molecules bound to the I- and τ -sites. The second region was identified via the analysis of a mutant bearing an alanine substitution for a conserved arginine at residue 281 (R281A) in the box VII motif within domain III. Like the W6A-substituted protein, the R281A mutant was poorly retained on a supercoiled plasmid containing *oriC*, suggesting that this arginine is necessary for self-oligomerization of DnaA. The latter observations correlate with structural studies of *Aquifex aeolicus* DnaA (lacking residues 1–76), in which domain III of one molecule interacts with this domain in the adjacent molecule in the DnaA oligomer. In this structure, DnaA assembles as a right-handed helical filament in which a separate arginine at position 285 in box VII interacts with ATP bound between adjacent protomers.

HU or DiaA Stabilizes DnaA at *oriC*

Recent experiments indicate that other proteins stabilize the DnaA oligomer bound at *oriC*. One protein is HU, a dimer that binds nonspecifically to DNA to form the nucleoid. The composition of HU is influenced by the growth phase of a culture. In early log phase, the α_2 dimer predominates, followed by the relative prevalence of the $\alpha\beta$ heterodimer during mid-log growth. The β_2 dimer becomes the principal form of HU as cells enter stationary phase. During initiation, HU was originally found to stimulate the DnaA-dependent unwinding of the 13-mer region in *oriC*. Despite HU's nonspecific DNA-binding activity, it was localized at or near *oriC* by immunoelectron microscopy. Recent work showed that HU interacts via its α subunit with the N-terminal region of DnaA to stabilize the DnaA oligomer at *oriC*. These *in vitro* results provide an explanation for these earlier observations and are supported by *in vivo* evidence that mutants of *hupA*, which encode the α subunit of HU, initiate at abnormal times in the bacterial cell cycle. As this phenotype of asynchronous initiation is also observed with other mutations that affect the function of either DnaA or *oriC* to modulate the frequency of initiation, these results suggest that DnaA oligomerization is essential for initiation to proceed normally.

Like HU, DiaA also stabilizes DnaA at *oriC*. Apparently, each protomer of the DiaA tetramer interacts with the N-terminal region of DnaA to stabilize it at the low-affinity I- and τ -sites. DiaA was originally identified in a genetic method to obtain mutations that suppressed the lethal effect caused by DnaAcos, a mutant DnaA that hyperinitiates. A simple explanation is that the lack of DiaA function leads to the diminished stability of DnaAcos oligomerized at *oriC*, which reduces the frequency of initiation to a level that no longer interferes with viability. Similar to mutants in the α subunit of HU, *diaA* mutants initiate asynchronously, so DiaA is physiologically important. That both HU and DiaA stabilize the DnaA oligomer suggests that conditions may arise *in vivo* when HU is favored over DiaA or the converse.

DnaA-Dependent Unwinding of the AT-Rich Region of *oriC* and Proteins That Modulate This Process

Bound to *oriC*, DnaA then unwinds the AT-rich region carrying the 13-mers near the left border. As DnaA complexed to ATP γ S is as effective as DnaA–ATP, nucleotide hydrolysis is not required. However, DnaA–ADP is essentially inactive. Considering that domains III and IV of *Aquifex aeolicus* DnaA assemble into a helical filament in the presence of ATP, whereas it forms a ring-like structure with ADP, ATP bound between adjacent molecules of the DnaA oligomer alters the conformation of domain III to prevent the flat ring arrangement. As the interior of this DnaA oligomer contains positively charged surfaces, a proposed model is that one or more basic residues bind to the negatively charged unwound DNA. In support, an alanine substitution for lysine 245 that is positioned on the interior surface of the filament leads to a specific defect in unwinding. Alanine substitutions of other basic residues (lysine 223 and lysine 243) are also defective in unwinding and in self-oligomerization to support the model that the DnaA oligomer binds to and stabilizes the unwound region of *oriC*. A prediction of this model is that all mutant DnaAs that are defective in self-oligomerization should be unable to unwind *oriC*. However, mutants bearing W6A or R281A substitutions are impaired in self-oligomerization, yet they remain as active as wild-type DnaA in *oriC* unwinding.

HU, DiaA, or IHF stimulate the DnaA-dependent unwinding of *oriC*. Stimulation by HU or DiaA correlates with both their interaction with residues in the N-terminal region (domain I) of DnaA and their ability to stabilize the DnaA oligomer at *oriC*. As IHF is known to bend DNA and also stimulate the binding of DnaA to the weaker sites in *oriC*, DNA bending by IHF at the IHF site in *oriC* may stabilize the DnaA oligomer by facilitating the interaction between or among DnaA molecules. By comparison, Fis obstructs the binding of DnaA to the low-affinity sites to inhibit the unwinding of *oriC*.

DNA-binding protein from starved cells (Dps) is expressed in response to oxidative stress and accumulates in starved cells. *In vivo*, Dps causes less frequent initiations. Biochemically, this protein interacts with the N-terminal region of DnaA and also inhibits the unwinding of *oriC*. These results support a model which proposes that Dps acts as a checkpoint during oxidative stress to reduce the frequency of initiation. This checkpoint may provide time for cells to repair the oxidative damage to the genome before it is duplicated.

Other Proteins Required for Initiation

DnaC

Similar to DnaA, DnaC is a member of the AAA+ ATPase family. Although many AAA+ proteins are ring-shaped oligomers, DnaC is purified as a monomer. Several studies showed that DnaC binds ATP, albeit with low affinity ($K_D \sim 8 \mu\text{M}$), and is a weak ATPase. To support the idea that ATP binding by DnaC is essential, genetic studies showed that missense mutations in each AAA+ motif impair DnaC function. *In vitro* work indicated that substitution of a conserved lysine with arginine in the Walker A box results in undetectable ATP binding and inactivity in DNA replication of an *oriC*-containing plasmid.

Recent work revealed that one of the AAA+ motifs, named box VII, appears to coordinate ATP hydrolysis with conformational changes that lead to the dissociation of DnaC from DnaB at *oriC*. Specifically, independent alanine substitutions for two conserved arginines in the box VII motif severely impaired DnaC in DNA replication by rendering the mutant proteins unresponsive to the signal that normally induces DnaC to dissociate. This signal appears to involve primer formation, defining a discrete event in the transition from initiation to the elongation phase of DNA replication.

DnaC also binds weakly to single-stranded DNA (ssDNA). This interaction, which is stimulated by ATP, has been measured by ultraviolet (UV)-crosslinking, or sensitive methods of fluorescence anisotropy, or surface plasmon resonance (SPR). If DnaC binds to the unwound region of *oriC*, this activity may help to load DnaB at *oriC*.

DnaB and the DnaB–DnaC Complex

DnaB is the replicative helicase for the *E. coli* chromosome, and for many plasmids and bacteriophage that use *E. coli* as a host. For DnaB to load at *oriC*, the helicase must be complexed with DnaC. However, DnaC bound to DnaB inhibits its helicase and ATPase activity, so DnaC must dissociate for DnaB to become active. Bound to ssDNA, the functional form of DnaB is considered to consist of six protomers assembled into a ring-like structure through which the ssDNA passes. Recent reports suggest how members of this helicase family unwind DNA. Structural studies reveal that each DnaB protomer has a RecA-like fold contained in its larger C-terminal domain and a smaller N-terminal domain. Via a domain near its N-terminus, DnaC binds to the larger domain of DnaB to form the DnaB–DnaC complex.

Loading DnaB Helicase

Following the unwinding of *oriC*, DnaA loads a single DnaB–DnaC complex onto each separated strand within *oriC* of a supercoiled plasmid to form an intermediate named the pre-priming complex. Loading appears to be a concerted event because replication forks move bidirectionally even when DnaB is at a subsaturating level. The loading process can also be measured with an ssDNA named M13 A-site that carries a DnaA box in a hairpin structure. DNA replication of this SSB-covered DNA requires the binding of DnaA to the hairpin, followed by loading the DnaB–DnaC complex. Primer formed by primase and DNA synthesis by DNA polymerase III holoenzyme converts the ssDNA to duplex form.

Based on the following evidence, two regions of DnaA appear to interact with DnaB to load the helicase. First, a monoclonal antibody that binds to an epitope within residues 111–148 inhibits both the binding of DnaA to DnaB, and DNA replication of the ssDNA and of an *oriC*-containing plasmid. Deletion analysis further refined this region to residues 130–148 near the N-terminus of domain III. The second interacting region of DnaA is within domain I. Mutant DnaAs carrying an E21A or F46A substitution are active in assays of DnaA function that do not also involve the DnaB–DnaC complex. In contrast, these mutants are essentially inactive in DNA replication of M13 A-site DNA, supporting the conclusion that the respective wild-type residues directly contact DnaB during helicase loading. In the nuclear magnetic resonance (NMR)

structure of domain 1 of *E. coli* DnaA, these residues lie in a solvent-exposed surface formed by the second and third α helices near the N-terminus.

Of interest, mutant DnaAs bearing W6A, or R281A substitutions are as active as DnaA⁺ in binding to and unwinding *oriC*, but are inactive in initiation at *oriC* due to a specific defect in self-oligomerization. In contrast, the mutants support DNA replication of M13 A-site ssDNA, suggesting that they are able to interact with DnaB. Apparently, DnaA oligomerization is necessary to load DnaB at *oriC* but not at the hairpin, at which only one or two DnaA molecules appear to bind in order to load a single DnaB helicase complexed to DnaC onto the ssDNA. Presumably, the DnaA oligomer at *oriC* forms a structure required to load both DnaB molecules.

Earlier studies of DnaB and DnaC have assumed that the functional form of the DnaB–DnaC complex contains six DnaC molecules per DnaB hexamer. Recent work suggests that the complex assembled at *oriC* contains three DnaC monomers per DnaB hexamer. These latter results are similar to those describing the initiation of DNA replication of bacteriophage λ , which encodes λ P protein that substitutes for DnaC. This viral DnaC analog forms a complex with DnaB, and even displaces DnaC from the DnaB–DnaC complex in the process of loading DnaB at the λ replication origin. Like the DnaB₆–DnaC₃ complex at *oriC*, the complex of λ P protein bound to DnaB contains three λ P monomers per DnaB hexamer. These similarities suggest that the helicase loading process at *oriC* and at the λ replication origin is comparable.

Other experiments showed that primer formation by primase, which interacts with the smaller domain of DnaB during primer synthesis, leads to the dissociation of DnaC bound to the larger C-terminal domain of DnaB. These results suggest that the interaction of primase with DnaB at *oriC* coupled with primer synthesis induce a conformational change in the helicase that causes DnaC to dissociate. Once DnaC has left, the helicase can begin to unwind the parental DNA.

Events after Initiation

Primer Formation and DNA Replication

Following the dissociation of DnaC from DnaB at *oriC*, one helicase molecule translocates clockwise on the circular bacterial chromosome while the other moves in the opposite direction. Each DnaB helicase encircles one strand of the duplex DNA and moves in the 5'-to-3' direction relative to this ssDNA as it unwinds the parental duplex. The occasional interaction of DnaB with primase leads to primer synthesis; several recent reports suggest how DnaB and primase coordinate their functions. A dimeric DNA polymerase III holoenzyme at each replication fork then extends the primers to duplicate the chromosome. Comparing bacteria with eukaryotes, it is remarkable that organisms in separate kingdoms utilize similar biochemical mechanisms of initiation of DNA replication.

Summary and Perspective

The molecular mechanism of initiation of DNA replication in *E. coli* can be separated into discrete steps. The major steps involve the recognition of the replication origin (*oriC*) by DnaA followed by the loading of DnaB helicase. For DnaB to

begin to unwind the parental duplex DNA, DnaC must dissociate from DnaB, which leads to the assembly of the replication fork machinery that is responsible for duplication of the bacterial genome. Fifty-eight years ago, Watson and Crick predicted that each parental DNA strand would serve as the template for the synthesis of the complementary strand. We now understand some of the molecular details of this process. Interested readers are invited to read other articles that review how DNA replication is regulated at the stage of initiation so that DNA replication occurs only once per cell cycle.

Glossary

Closed-circular DNA DNA in which the double helix forms a continuous circular structure with no ends nor any interruptions in either strand.

DNA replication The process by which a given DNA molecule duplicates itself. This process occurs in different ways depending on the form of DNA and the enzymes and factors supporting replication.

Mitochondria The organelles in cells primarily responsible for energy production.

Mitochondrial DNA (mtDNA) The genome of mitochondria; every species has a characteristic mtDNA sequence.

Origin A DNA sequence region in which new DNA synthesis begins.

Promoter A DNA sequence recognized by enzymes and factors that copy genes into RNA molecules. Like an origin, a promoter marks the beginning of a nucleic acid synthesis event.

Transcription The overall process by which DNA sequence is copied into RNA sequence. This is the first major step in gene expression.

Mitochondrial Constituents and Their Functions

Mitochondria comprise an estimated 1500 different macromolecules, including mitochondrial DNA (mtDNA), mitochondrial RNA (mtRNA), and proteins.

mtDNA

Although certain cells can exist without mtDNA under special nutrient and growth conditions, where oxidative phosphorylation activity is not essential, in all other cases, mtDNA is needed. This is due to the fact that mtDNA encodes some of the proteins necessary for mitochondrial function in energy production. The sizes of mitochondrial genomes are quite broad. Vertebrate mtDNAs are typically 16–18 kb in size, with yeast mtDNA being several times larger. Plant mtDNAs can be 30-fold larger than vertebrate mtDNA. In addition, the number and identity of mtDNA genes are not constant across all mtDNAs. Human (and vertebrate) mtDNAs contain 37 genes, of which 13 are for proteins involved in bioenergetics. Although larger mtDNAs can contain more genes, the amount of coding information is not directly linear with genome size.

RNA

The RNA inside the mitochondrion is almost exclusively that which is encoded by mtDNA. For mammals, this generally includes two ribosomal RNAs (rRNAs) and 22 transfer RNAs (tRNAs). These 24 RNAs are thought to be necessary and sufficient to support fully the mitochondrial translation machinery, responsible for decoding the additional 13 mammalian mRNAs for mtDNA-encoded proteins.

Other RNAs, encoded by nuclear genes, include additional tRNAs, in cases where mtDNA contains an insufficient number of its own tRNA genes, and 5S rRNA. In addition, certain RNA-processing activities, consisting of enzymes with nucleus-encoded RNA components, have been implicated as participants in processing mtRNA sequences. These include an RNase P

for processing tRNA precursors and an RNase that cleaves mtRNA sequences at the origin of leading-strand DNA replication. This latter activity, RNase MRP, is thought to provide 3'-primer RNA ends for elongation by mtDNA polymerase.

Protein

The protein components of mitochondria are of several classes. Although mitochondria play key roles in apoptosis, calcium regulation, iron metabolism, and the synthesis of amino acids, sterols, and heme, the classic principal function of the organelle is energy production. It is, therefore, not surprising that all of the mtDNA-encoded proteins participate in the formation of one or another of the several bioenergetic complexes that support the chain of reactions leading to adenosine triphosphate (ATP) production. Although the vast majority of mitochondrial proteins are encoded by nuclear genes, those encoded by mtDNA are essential and there are no nuclear genes present that can substitute for a loss of mtDNA.

The nucleus-encoded proteins that comprise the bulk of mitochondrial proteins fall roughly into two classes. One class is devoted to the task of energy production and mitochondrial function, including maintenance and expression of mtDNA. The second population consists of structural elements that provide the infrastructure that maintains basic mitochondrial morphology, mobility, and organelle physiology. Most mitochondrial proteins, being nuclear-gene products, are produced by translation on cellular ribosomes and then targeted to mitochondria by their sequence (the most common feature directing the process is a signal sequence at one end of the protein, the amino terminus). Physical importation of the protein involves specific portions of the mitochondrion's inner and outer membranes that form ports for entry of these proteins. Initially, a general internalizing import mechanism applies to most proteins regardless of their final destination within the mitochondria. This is followed by other mechanisms leading to sorting of a protein according to its function.

Replication of the Mitochondrial Genome

Replication of mtDNA occurs within the confines of the mitochondrial-organelle network, which is usually organized dispersively throughout the cell's cytoplasm. As such, it represents a separately managed genome, physically and functionally distinct from nuclear DNA replication. The cellular copy number of mtDNA varies according to cell type. For example, mature lymphocytes have a few hundred mitochondrial genomes, whereas mammalian oocytes contain tens of thousands. Unlike nuclear DNA replication, which is subject to cell cycle control, it appears that mtDNA is able to initiate and complete a round of replication in dividing cells without restriction. Furthermore, mtDNA needs to be continually replenished in somatic cells due to organelle turnover. Such cells normally do not divide and, hence, do not replicate their nuclear DNA.

Mammalian mtDNA

The historic replication model posits that leading-strand replication of mammalian mtDNA begins at closely spaced, defined sites located downstream from a major transcription promoter and proceeds unidirectionally with displacement of the parental leading strand until approximately two-thirds of the closed circular mtDNA have been copied (Figure 1). As a consequence, the replication fork passes a major origin for lagging-strand synthesis, leaving it in single-stranded form. Displacement as a single strand is thought to allow the characteristic secondary structure of this origin to occur, thereby permitting initiation of lagging-strand synthesis. A natural consequence of the separate and distinct locations of the two origins is that the two segregated progeny mtDNA circles are of two types: one a duplex circle with a newly synthesized leading strand and the other a gapped circle with a partial newly synthesized lagging strand. In each case, the final steps of synthesis and closure result in the mature closed circular mtDNA products.

Convincing biochemical isolation and characterization of mammalian mtDNA began in the 1960s. The key technical breakthrough was the use of dye-salt buoyant density centrifugation to isolate even relatively rare closed-circular DNAs in highly purified form. This technique was exploited to perform mtDNA analyses by sophisticated analytical centrifugation techniques, by electron microscopy, and eventually by gel electrophoresis. It is fortuitous that mammalian mtDNA molecules are small enough to be easily manipulated and analyzed by a variety of techniques.

Unique to mammalian mtDNA and a few viral DNA genomes is a bias in the content of guanosine plus thymine in one strand of the double helix compared to the other strand. A consequence of this situation is that the two strands of mammalian mtDNA can be physically separated to an extent that allows their individual identification. Therefore, one can isotopically label mtDNA and directly assay the extent of mtDNA synthesis that has occurred in each strand.

Perhaps the most signature feature of mammalian mtDNA is the displacement loop (D loop). The D-loop nomenclature follows from the fact that closed-circular mtDNA contains a region of varying size, depending on the species, in which

Figure 1 Diagram of mtDNA replicative intermediates. In the strand-displacement model closed-circular mtDNA (C-mtDNA) is in equilibrium with D-loop mtDNA (D-mtDNA). Productive replication is defined by elongation of the leading strand (red), which progresses around the genome (dashed red; Exp-D) until exposure of the major lagging-strand origin, which sponsors initiation of synthesis in the counterclockwise direction. End products are the new α - and β -circles, which are finished to closed circles (E-mtDNA). Superhelical turns are introduced (C-mtDNA) and finally a new D loop is synthesized. There is a rapid conversion back and forth between D-mtDNA and C-mtDNA. In mouse tissue culture cells the predominant form of mtDNA (>75%) is D-mtDNA.

leading-strand DNA synthesis has initiated and elongated to a size between 0.5 and 1 kb. Molecules exhibiting progressive growth of this nascent leading strand, approaching full genomic size, were identified and argued as support for the proposed model for replication.

Lagging-strand synthesis is revealed by the appearance of duplex DNA within the context of the ever-increasing displaced parental-single strand. A preferred initiation site is located about two-thirds of the genomic distance away from the D-loop origin of leading-strand synthesis. Recent studies have suggested that other additional sites can serve as points of lagging-strand DNA replication initiation and thereby provide a broader range of duplex replicative intermediates.

Alternative models for human mtDNA replication have been proposed mainly by inferring replicative intermediate structures based on migration patterns of mtDNA under two-dimensional gel electrophoresis. The currently postulated alternative model is one in which leading-strand synthesis is very similar to that depicted in Figure 1. The unusual feature of the model is that lagging-strand mtDNA synthesis is preceded by

extensive RNA synthesis which is somehow converted to DNA by processing or displacement of significant stretches of this RNA. Studies from other laboratories have also reported significant amounts of mtRNA sequence co-isolating with mtDNA. Some, but not all, of these RNAs have a suitable 3'-end for extension into a DNA strand by mtDNA polymerase.

Important insights required for a full elaboration of mtDNA replication mechanics will be aided by the development of robust *in vitro* replication systems using cloned and highly purified components. Indeed, recent *in vitro* work has verified, at the nucleotide level, prior studies over the last several decades that mapped the exact 5'-end positions of newly synthesized strands of mtDNA.

Future Studies

In contrast to studies on mtDNA, the mitochondrial system has been challenging with respect to identifying, purifying, and characterizing the critical proteins and other factors that sponsor mtDNA replication. A principal reason for this is that although low-abundance mammalian mtDNA can be successfully purified to a high state because of its closed circular physical form, in general, the mitochondrial proteins involved in mitochondrial nucleic acid syntheses can be similar, with regard to their purification properties, to their much more abundant nuclear counterparts. A further complication is that while most activities are unique to mitochondria, others are shared with the nucleus (e.g., RNase MRP and DNA topoisomerase III α). With the current availability of mammalian genomic sequences, and cloning and expression technologies, it should be possible to make significant advances in this area. A partial listing of known and predicted activities includes mtDNA and mtRNA polymerases, transcription factors, single-strand DNA-binding protein, specialized RNase activities, helicases, and topoisomerases.

It is now clear that mitochondrial function and the integrity of normal mtDNA are important for normal physiology in mammals. There are numerous reports of human diseases that have mtDNA mutations, and even loss of mtDNA, as the underlying basis for what is usually manifested as neuromuscular disorder phenotypes. It will be important to learn the nature and rate of mtDNA turnover in different cells and tissues. Unlike nuclear DNA, which is not replicating in non-dividing cells, mtDNA continues in its need to replicate due to continuous turnover and renewal of the mitochondrial organellar population. Thus, at least the opportunity to accumulate mutations in mtDNA due to replication errors during an individual's lifetime can be appreciated. Knowledge of the global pattern of mtDNA-turnover rates could prove valuable in predicting risk factors for human mitochondrial disease.

A full understanding of the role and dynamics of small D-loop formation at the leading-strand origin of replication remains to be determined (Figure 1). This unique, species-specific structure is aggressively synthesized and is immediately adjacent to the promoters of transcription. It is likely that both RNA processing and termination events occur in this region of the genome. The RNA processing activity that recognizes and cleaves mtRNA primer sequences contains an RNA encoded by a nuclear gene. Recent studies have begun to reveal the mechanism of RNA import.

The identification and structural determination of the mammalian mtDNA polymerase subunits that comprise the holoenzyme pave the way for the future important studies on elucidating the bases for how the many known cases of mutations in the enzyme can cause human pathological conditions.

There are now a number of studies that are identifying the key activities that regulate the fission and fusion of individual organelles. This will likely involve further consideration of how the mitochondrial network travels along microfilaments and is positioned within the cellular cytoplasm. In turn, it will be important to learn more about the precise location of intracellular mtDNA-replication sites to determine if replication is site specific or can occur generally.

Yeast and Others

Historically, the yeast system has been the most widely used to study almost all aspects of mitochondrial biogenesis. It has provided a wealth of information on bioenergetics, organelle assembly, protein import, and other areas of mitochondrial biology, including the details of mtDNA gene expression.

However, studies of mtDNA replication in yeast have been challenging due, in part, to the plasticity of the genome and the very aggressive rate of recombination of yeast mtDNA in cells. Thus, the isolation and analysis of productive replicative intermediates have proved much more difficult than for mammalian systems with their small genomes and almost complete absence of recombination, including the nucleases usually associated with breakage and rejoining of DNA strands. Nevertheless, there are a few intriguing similarities between yeast and mammalian mtDNAs with regard to potential yeast mtDNA origins resembling origin sequences in D loops. It will be interesting to learn whether origins of replication have been conserved over this period of evolution, or whether other roles for these sequences, such as attachment to membranes to facilitate segregation of mtDNA molecules after replication, are the driving force for these similarities. In this regard, recent studies have suggested that mtDNA can be isolated in close association with specific proteins, which may be key to understanding genomic placement in the organelle.

This article is a revision of the previous edition article by Darren M. Gowers and Stephen E. Halford, volume 1, pp. 772–777, © 2004, Elsevier Inc.

Glossary

Palindromic DNA A DNA in which the 5′–3′ sequence of one strand is the same as that of the complementary strand.

Recognition site A sequence of nucleotide bases recognized by a restriction enzyme.

Restriction digest The cleavage of DNA molecules into defined fragments by the action of a (Type II) restriction enzyme.

Restriction mapping Placing the series of DNA fragments from a restriction digest into the order in which they occur along the DNA.

Restriction–modification (RM) The bipartite bacterial defense system. Unmethylated phage DNA is hydrolyzed at specific sites by a restriction enzyme; host DNA containing the same sequences is guarded from destruction by methylation from a modification methyltransferase.

S-Adenosylmethionine (AdoMet) The cofactor for methyltransferases.

History

The ability of bacteria to defend themselves from viral infection was first reported by Luria and by Bertani in 1952 and 1953. The latter noted that some strains of *Escherichia coli* could restrict the growth of bacteriophage λ . This was accounted for a decade later by W. Arber, who proposed the existence of restriction–modification (RM) enzymes; the restriction enzymes were envisaged to cleave DNA in response to a particular sequence of bases, but only if the sites had not been protected by prior modification.

A landmark was attained in 1970, when H. O. Smith identified a novel restriction enzyme that cleaved DNA at a specific sequence. (The restriction enzymes identified previously were all Type I systems that cleave DNA at nonspecific sequences.) In collaboration with D. Nathans, he showed that this enzyme could be used to dissect DNA into discrete fragments. In 1978, Arber, Nathans, and Smith shared the Nobel prize in medicine. At that time, nearly 50 Type II restriction enzymes had been discovered. Today, that number stands near 4000. The early availability of restriction enzymes as off-the-shelf reagents heralded the age of recombinant DNA technology.

Classification

At least four distinct categories of RM systems have been identified from their subunit compositions and their modes of action: Types I, II, III, and IV. This article focuses on the Type II systems. In brief, most Type II systems consist of two proteins: a restriction endonuclease that, in the presence of Mg^{2+} , cleaves DNA at a particular sequence, its recognition site; and a modification methyltransferase that blocks restriction activity by transferring a methyl group from S-adenosyl methionine (AdoMet) to a particular base in the recognition site. Only the nucleases from Type II systems cleave DNA at specific positions and it is these, unlike the Type I and the Type III enzymes, which have the myriad applications in recombinant DNA technology.

The enzymes within the Type II category display a variety of reaction mechanisms and subunit compositions. Consequently, they can be categorized into various subtypes, for example, the Type IIS, the Type IIB, the Type IIE, and the Type IIF enzymes.

Discovery of New RM Systems

The value of Type II restriction enzymes for DNA manipulations has driven extensive searches for more enzymes of this sort. The standard method for identifying new restriction enzymes has been to screen bacterial lysates for endonucleases that cleave DNA into discrete fragments. Phage or adenoviral DNA are often used as test substrates. The recognition sites are then determined by sequencing methods. About one-half of the bacterial strains tested in this way are found to have an RM system, in some cases two or three such systems. But if the enzyme fails to cleave the test DNA for any reason, it will not be detected by this procedure. For example, if it was present at too low a level or if it required a special substrate or an unusual cofactor, it would escape detection.

In recent years, new RM systems have been identified by analyzing the genome sequences of bacteria. Such analyses show that almost all bacteria possess multiple candidates for RM genes, in some cases over 20 such candidates. Over one-third of the candidates are for Type II systems, with the remainder Types I, III, or IV. Subsequent studies showed that a high proportion of the candidates for the Type II RM systems did indeed encode active enzymes, though in some instances only the methyltransferase was active.

Organization of Genes

Modification and Restriction Genes

The Type II systems generally feature two separate genes: one for the restriction enzyme and one for the modification

enzyme. In all such systems examined to date, the gene for the endonuclease is adjacent to that for the methyltransferase, although the order of the genes varies between systems. In some cases, they are in head-to-tail orientation and in others head to head or tail to tail.

Modification genes from different Type II systems are often homologous to one another. In many cases, the methyltransferase genes encode 10 highly conserved blocks of amino acid sequence which are involved directly in catalysis and AdoMet binding. Another block of protein sequence, which is not conserved, is involved in DNA recognition.

The restriction genes in the Type II systems are never homologous to the modification gene from the same system, despite coding for proteins recognizing the same DNA sequence. Moreover, the restriction enzymes from different Type II systems generally have dissimilar amino acid sequences, apart from certain enzymes with the same recognition site. The only well-conserved feature is the motif Pro-Asp-X₁₀₋₂₀-(Asp/Glu)-X-Lys (where X is any amino acid), which is often found at the active site. The aspartate and glutamate residues form part of the binding sites for the Mg²⁺ ions.

There are, however, many Type II systems that deviate from the standard pattern of one modification gene and one restriction gene. For instance, some systems employ two modification enzymes, one for each strand of the DNA. Others have two restriction genes to encode an enzyme comprising two different subunits. In further cases, one gene encodes a single polypeptide with both modification and restriction activities.

Regulating RM Expression

Whenever a bacteria gains a new RM system, expression of the RM genes has to be stringently coordinated. The methyltransferase must be produced first, to protect all the recognition sites in the chromosome, before significant amounts of the endonuclease are made. To do this, some Type II RM systems, such as PvuII and BamHI, contain a gene upstream of the restriction gene that codes for a protein that regulates gene expression in this manner.

The Type II Restriction Endonucleases

Recognition Sequences

The recognition sequences for many – but by no means all – of the Type II restriction enzymes possess three attributes (Table 1). First, the sites are usually 4–8 bp long. Second, the sites are palindromic: they read the same in 5'–3' directions on both strands. Third, the sites are fully specified, in that every position in the sequence is occupied by a particular base. Yet there exist numerous exceptions.

For some enzymes, the recognition sequence is degenerate, in that certain positions can be occupied by alternate bases. For example, the recognition sequence for Cfr10I (Table 1) has either G or A at its 5'-end and either C or T at its 3'-end. Similarly, the central base pair in the target site for EcoRII can be either an A:T or a T:A. For some systems, the recognition sequence is discontinuous, for example, SfiI (Table 1). Such sites contain two blocks of specified sequence interrupted by a section of unspecified sequence but defined length that varies

from just 1 bp (e.g., HinfI at GANTC) to 9 bp (e.g., XcmI at CCA(N)₉TGG). In most cases, the specified base pairs in the degenerate and in the discontinuous sites are still symmetrical palindromes.

Some recognition sites are truly asymmetric. For example, the 5'–3' sequence in the top strand of the recognition site for BbvCI is not the same as the bottom strand (Table 1). Many enzymes that recognize asymmetric sequences cleave the DNA some distance away from the site, at fixed positions on one side of the site. These are called the Type IIS enzymes. One example is FokI at GGATG(9/13); it cleaves 9 bases downstream from its site on the top strand and 13 bases away on the bottom strand (Table 1). However, others cut just one strand, for example, Nt.BstNBI (Table 1). Conversely, certain enzymes that recognize asymmetric sequences cleave both upstream and downstream of the recognition site, for example, BcgI (Table 1). They cut four phosphodiester bonds in their reactions to liberate a small DNA fragment, 32 bp in the case of BcgI, which contains the intact recognition site. Such enzymes belong to the Type IIB category.

The ~4000 known enzymes have only ~290 different recognition sequences, so enzymes from different species often have the same recognition site. Those that cut at exactly the same position are called isoschizomers; for example, HhaI and CfoI both cut GCG↓C. Those that cut at different positions within the same sequence are called neoschizomers; HinfII, which cuts G↓CGC, is thus a neoschizomer of HhaI.

Protein Structures

The enzymes that recognize palindromic DNA sequences are generally dimers of identical subunits. They interact with their recognition sequences symmetrically so that all the contacts between one subunit of the protein and one-half of the recognition site are duplicated by the second subunit with the other half of the DNA. One active site in the dimer is positioned against the scissile phosphodiester bond in one strand of the DNA and likewise the second active site on the other strand.

The structures of numerous Type II endonucleases, and their complexes with DNA, have been determined by X-ray crystallography. As with most other proteins that act at specific DNA sequences, restriction enzymes recognize their target sequences primarily by multiple hydrogen bonds to the bases in the major groove of the DNA. However, the restriction enzymes do not usually employ the elements of protein structure that are common among DNA-binding proteins, such as the helix–turn–helix or the zinc finger. Instead, their DNA-recognition elements encompass a wide variety of nonstandard structures, including loops, sheets, and helices. These also differ considerably from one enzyme to the next. In some cases such as EcoRV, recognition of the specific sequence also depend on deformations to DNA structure.

Despite the overall dissimilarity in their amino acid sequences and their differences in their structural elements for DNA recognition, some Type II restriction enzymes have similar tertiary structures in terms of the overall fold of the polypeptide chains, for example, EcoRI has a similar fold to BamHI and likewise EcoRV to PvuII. Similar folds have since been found in many other proteins that act on DNA, including enzymes involved in replication, recombination, repair, and transposition.

Table 1 Recognition sites for Type II restriction endonucleases

Site	Enzyme	Genus	Recognition site
<i>Palindromic</i>			
<i>4 bp</i>			
5' Overhangs	Sau3AI	<i>Staphylococcus aureus</i>	5' ↓G-A-T-C 3' 3' C-T-A-G ↑ 5'

Cleavage of Specific DNA Sequences

Enzymes such as EcoRV or BbvCI find their recognition sites in long DNA molecules by first binding to the DNA anywhere along the chain and then translocating to the recognition site by intramolecular pathways. The transfer seems to occur primarily by multiple rounds of dissociation and re-association events within the same chain. However, one-dimensional diffusion along the chain may also play a role, particularly over short distances of DNA. Its role is primarily to scan the DNA over the 10–100 bp immediately adjacent to the site of each re-association event. Once at the recognition site, each active site in the dimeric enzyme catalyzes the hydrolysis of its target phosphodiester bond in independent reactions. Both reactions are usually complete within the lifetime of the DNA–protein complex, so the initial product released from the enzyme is the DNA cut in both strands. On the other hand, if the complex dissociates before both strands

are cut – for example, in reactions at high ionic strength – DNA cleaved in one strand is liberated.

With very few exceptions, the Type II endonucleases require Mg^{2+} for their reactions. Some other metal ions, such as Mn^{2+} or Co^{2+} , give low levels of activity but others, such as Ca^{2+} , give no activity at all. The Mg^{2+} ions play direct roles in the catalytic reaction, but the precise roles vary from enzyme to enzyme. Some, such as EcoRI, seem to have one metal ion at each active site, whereas EcoRV, BamHI, and many others use two ions. There exist, however, several Type II enzymes that display their maximal activities with Ca^{2+} rather than Mg^{2+} and one, BfiI, that has no requirement for any divalent metal ion.

The hydrolysis of phosphodiester bonds by Type II endonucleases yields termini with 5'-phosphate and 3'-hydroxyl groups. Some enzymes introduce staggered breaks into the DNA, leaving fragments of double-stranded DNA with single-strand extensions at either their 5'-ends (e.g., EcoRI in Table 1)

or their 3' end (e.g., PvuI in Table 1). Others cut both strands at equivalent positions, producing blunt-ended fragments (e.g., EcoRV in Table 1).

Interactions with Nonspecific DNA

The Type II restriction enzymes are extremely specific for their cognate sequences. They cleave their recognition sites over a million times more rapidly than DNA sequences that differ from the recognition site by just 1 bp. Surprisingly, this specificity in catalysis need not be accompanied by an equivalent specificity in DNA binding. In the absence of Mg^{2+} ions, many restriction enzymes bind to all DNA sequences with similar affinities. Their extraordinary specificities for DNA cleavage arise instead from the catalytic reaction, with only the cognate DNA giving rise to a catalytically competent enzyme- Mg^{2+} -DNA complex. For example, the complex of EcoRV with non-specific DNA has a low affinity for Mg^{2+} , whereas its complex with specific DNA has a high affinity for Mg^{2+} , so only the specific DNA is cleaved.

Certain reaction conditions can, however, enhance the activities of these enzymes at alternative sites. This is termed star activity. The star sites are generally sequences that differ from the recognition site by 1 bp. Sequences differing in two or more positions are normally resistant even under star conditions. The conditions that cause star activity include high pH, low ionic strength, the addition of organic solvents, and the replacement of Mg^{2+} with Mn^{2+} .

Subsets of Type II Restriction Enzymes

In recent years, many Type II enzymes have been found to have distinctive properties and have been classified into subsets, a fraction of which are noted below. A large number of these enzymes have to interact with two copies of their recognition site before cleaving DNA. The restriction enzymes that need two sites are in effect double-checking the DNA to ensure that they cleave DNA only at the correct sequence.

Type IIS

Type IIS enzymes recognize asymmetric sequences and cleave the DNA at fixed positions downstream of the recognition site, typically 1–20 bp away. FokI (Table 1) is an archetype of the Type IIS enzymes. It is a monomeric protein containing two domains connected by a flexible linker: a DNA recognition domain that makes all of the contacts to the recognition site and a catalytic domain that has an active site capable of cleaving one DNA strand. To cut both strands, two monomers of FokI have to associate to a dimer via their catalytic domains to create a unit with two active sites. The dimer is formed most readily when both monomers are bound to separate FokI sites in the same DNA molecule. FokI is thus more active on molecules with two sites than on DNA with one site. This is a common feature of the Type IIS enzymes. Most of them cleave DNA with two target sites more rapidly than DNA.

An asymmetric sequence cannot be recognized by two identical subunits making identical interactions with the DNA, with each cutting one strand. Instead, the Type IIS enzymes

have evolved various strategies to cut both strands adjacent to their asymmetric sites. The mode of action of FokI, transient dimerization, is only one example. Others include: two active sites within a single polypeptide; a single active site that moves from one strand to the other; the recruitment of a separate DNA-cleavage subunit; and a tetrameric protein with four active sites that cut both strands at two separate sites.

Type IIE

Another subset of Type II enzymes is the Type IIE group, typified by EcoRII and NaeI, which consists of dimers of identical subunits. The interface between the subunits of the NaeI endonuclease has two binding clefts for the recognition sequence rather than the single cleft in enzymes such as EcoRV and BamHI. One cleft has the catalytic functions for DNA cleavage, but these are inactive unless the other cleft has bound another copy of the recognition site. Interactions spanning two DNA sites occur more readily with sites in *cis* on the same molecule of DNA than with sites in *trans* on different molecules. The Type IIE enzymes thus cleave DNA with two recognition sites faster than DNA with one site, but only one of the two sites is cut per turnover.

Type IIF

SfiI, Cfr10I, NgoMIV, and several other restriction enzymes show further differences from the orthodox pattern, and this group is now known as the Type IIF enzymes. They function as tetramers of identical subunits, two of which interact with one copy of a (usually) palindromic recognition sequence while the other two interact with a second copy. To cleave DNA, both binding sites must be filled with cognate DNA. Hence, like the Type IIE enzymes, the Type IIF enzymes interact with two copies of the target sequence, but, in contrast to the IIE systems, the IIF enzymes cut both sites in both strands. They thus cleave four phosphodiester bonds per turnover to convert a DNA with two sites into the product cut at both sites. They display optimal activity with sites in *cis* – the concurrent binding of the enzyme to sites in the same molecule of DNA traps the intervening DNA in a loop. Nevertheless, they can also act, albeit less efficiently, with sites in *trans* by bridging separate molecules.

Type IIB

By cutting both strands of the DNA on both sides of their recognition sites, the Type IIB enzymes such as BcgI (Table 1) cut four phosphodiester bonds at each recognition site. Moreover, like many other restriction enzymes, the IIB enzymes are more active against DNA with two recognition sites than DNA with a single site. They thus have the potential to cleave eight phosphodiester bonds per turnover. The IIB enzymes also differ from the orthodox enzymes in subunit composition. For instance, BcgI contains two different subunits: one carries both the endonuclease and methyltransferase activities while the other recognizes the cognate DNA. Other Type IIB enzymes contain a single subunit with endonuclease, methyltransferase, and DNA recognition functions. Moreover,

some require AdoMet for not only the methyltransferase but also the endonuclease activity.

The Type II Modification Methyltransferases

DNA Modification

The methyltransferases of Type II RM systems are altogether different from the partner endonucleases; their only commonality is recognition of the same DNA sequence. The purpose of the modification enzyme is to protect recognition sites in the host DNA from the restriction enzyme. They achieve this by transferring a methyl group from AdoMet to a particular base in the recognition sequence. Some methylate the carbon at position 5 (C5) of the cytosine ring, some the exocyclic amino group at position 4 in cytosine, and some the exocyclic amino group at position 6 in adenine. Each turnover of a modification enzyme methylates the recognition sequence in one strand. This is sufficient to block the activity of the restriction endonuclease. Hence, following semi-conservative replication of fully methylated DNA, the hemi-methylated daughter strands are protected. The unmethylated strand must then be modified by the methyltransferase before the next round of replication. Surprisingly, the methyltransferases from certain Type IIS R–M systems target only one strand and how these protect both of the newly replicated daughter chromosomes has yet to be explained.

The Methyltransferase Enzymes

The methyltransferases from Type II RM systems are monomeric proteins. The same enzyme methylates both strands of palindromic sites, but two methyltransferase functions are needed at asymmetric sites: one for the top strand and another for the bottom strand, though both activities are sometimes present in one polypeptide. The crystal structures of these enzymes have revealed two domains, one on either side of a DNA-binding cleft. One domain contains the DNA-recognition functions, which are unique to each methyltransferase, and the other the binding site for AdoMet and the catalytic residues for the transfer reaction.

The crystal structure of the HhaI methyltransferase bound to its recognition sequence revealed a novel perturbation of the DNA. Remarkably, the target cytidine had been swiveled completely out of its stacked conformation in the DNA helix and into the active site of the enzyme, deep in the catalytic domain. Other DNA-processing enzymes also use this mechanism, for example, the uracil DNA glycosidases in DNA repair. Base flipping may be a ubiquitous device used by enzymes that require access to the nucleotide bases in DNA that are otherwise buried in the double helix.

All methyltransferases use AdoMet as the methyl donor. With the cytosine C5 methyltransferases, the carbon must first be activated. This is achieved by forming a covalent bond between the adjacent C6 position on the cytosine and the thiol group of a cysteine in the active site of the protein. The subsequent transfer of the methyl group to C5 expels the cysteine from C6, thus breaking the covalent link between

protein and DNA. With the cytosine N4 and the adenine N6 methyltransferases, the exocyclic amino group may function directly as a nucleophile to attack the transferable methyl group of AdoMet.

Restriction Enzymes in the Laboratory

Various factors have contributed to the adoption of Type II restriction enzymes as essential research tools. The foremost is their specificity in cleaving DNA at fixed positions at particular sequences; that is, their abilities to recognize simple DNA sequences within any DNA molecule and to cleave the DNA at those sites without cleaving other sites to any detectable extent. Consequently, a restriction digest yields a discrete set of defined fragments determined by the locations of the recognition sites in the DNA molecule. Moreover, the resultant fragments of duplex DNA may, depending on the restriction enzyme being used (Table 1), possess single-strand extensions that are mutually complementary. Such fragments can then be ligated to other DNA molecules with the same single-strand extensions.

The applications of restriction enzymes have led to the emergence of several companies for whom restriction enzymes are the primary product line. The availability of these enzymes permitted far-reaching technical advances, such as the construction of recombinant DNA molecules, restriction mapping, DNA sequencing, restriction-fragment-length polymorphisms (RFLPs) and DNA fingerprinting. These techniques have proved to be invaluable for gene isolation and analysis, for genetic diagnosis and for genealogical tracking.

One feature of Type II nucleases that concerns users is their star activity (noted previously). Under altered conditions, the barriers that prevent the enzymes from cleaving DNA at non-cognate sites are less severe than those under optimal conditions. There is no general remedy for this, other than avoiding the conditions that cause it: low ionic strength, high pH, organic solvents, and Mn^{2+} . Nevertheless, it is proving possible to develop mutationally altered restriction enzymes that display considerably less star activity than the native forms.

A further concern is the fact that many restriction enzymes cleave DNA only after interacting with two recognition sites. Such enzymes have low activities against DNA molecules with one target site, but they can be activated against single-site substrates by adding oligonucleotide duplexes that have the recognition sequence.

Glossary

DNA translocation Movement of DNA through a region of protein, an energy-dependent process.

Methylation Modification of target base within the recognition sequence by the transfer of a methyl group from AdoMet.

Phase variation The high-frequency, reversible ON–OFF switching of gene expression that leads to changes in the expression of surface antigens.

Restriction DNA cleavage by a restriction enzyme within or outside the recognition sequence.

Organization of Genes and Regulation of Restriction Activity

A tight control of the potentially lethal activity of the restriction enzyme is ensured for efficient establishment of type III restriction–modification (R–M) systems in a cell. Two independent post-transcriptional regulatory mechanisms control the expression of restriction activity:

1. Modification activity is expressed immediately after the *res* and *mod* genes enter the cell, whereas the expression of restriction activity is delayed until the complete protection of cellular DNA is achieved by methylation. The expression of Mod subunit regulates the amount of restriction subunit present in the cell, suggesting that the correct folding of Res into an active and stable conformation is promoted by its interaction with the Mod subunit.
2. *In vivo* restriction activity is modulated by a decrease in the efficiency of translation and by varying ribosomal fidelity. For instance, EcoP1I restriction is drastically decreased by mutation in *rpsL* gene that encodes ribosomal protein S12, probably due to reduced translation efficiency.

It has been unequivocally shown that type III restriction enzymes, R.EcoP1I, R.EcoP15I, and R.PstII, occur as R_2M_2 complexes, while the companion DNA methyltransferases (MTases) occur as a dimer (M_2). In the case of R.EcoP15I and R.EcoP1I, the tetrameric R_2M_2 complex is stable at nanomolar concentrations *in vitro*. However, R.PstII occurs as R_2M_2 complex at high enzyme concentrations, while various subassemblies exist at low enzyme concentrations. Disassembly of PstII by the loss of a Res subunit is able to control relative modification/restriction activities. While both the EcoP1I and EcoP15I R–M systems are freely transferable from cell to cell by phage infection, conjugation, and transformation, horizontal transfer of the type III restriction enzyme, StyLTI, results in cell death. It is, thus, possible that these differences may reflect alternative routes to prevent auto-restriction by type III restriction enzymes.

Cofactor Requirements

Among the type III restriction enzymes that have been characterized to some extent, R.EcoP15I, R.EcoP1I, R.HinfII, and,

more recently, R.PstII require adenosine 5'-(γ -thiotriphosphate) (ATP) for DNA cleavage and possess sequence-specific ATPase activity. Nonhydrolyzable analogs of ATP, such as adenosine (β,γ -imido)triphosphate (AMP-PNP) or ATP- γ S, cannot replace ATP in the reaction. Interestingly, R.PstII has more relaxed nucleotide specificity and can cut DNA with guanosine triphosphate (GTP) and cytosine triphosphate (CTP) but not uridine triphosphate (UTP). While AdoMet is an absolute requirement for DNA cleavage by type I restriction enzymes, the requirement of AdoMet for DNA cleavage by type III restriction enzymes has been questioned. DNA restriction by R.EcoP1I requires exogenous addition of AdoMet, while the closely related R.EcoP15I has bound AdoMet and, therefore, presumably does not require the addition of this cofactor for DNA cleavage. The presence of different monovalent cations in assay buffers seems to influence the AdoMet requirement. In the presence of sodium ions, R.EcoP1I showed an absolute AdoMet requirement for DNA cleavage, whereas this was not the case in buffers containing potassium ions.

In addition, in the absence of AdoMet, R.EcoP1I showed nonspecific endonuclease activity that was further enhanced by the presence of AdoHcy (product of methylation reaction). Under these conditions, the requirement for two inversely oriented recognition sites does not seem to be necessary. Similarly, sinefungin, analog of AdoMet, supports DNA cleavage by R.EcoP15I and interestingly, the two-site requirement is not a strict prerequisite. Another study reports that with purified R.EcoP15I sinefungin has no effect. AdoMet is postulated to have three roles as far as type III restriction enzymes are concerned: (1) as a methyl group donor for DNA methylation, (2) as an allosteric activator of DNA binding, and (3) as a specificity factor, preventing unregulated cleavage of DNA substrates. The reasons for the discrepant findings on cofactor requirements of type III restriction enzymes remain unclear. Varying buffer conditions and duration of dialysis after purification or the host strains used could influence enzyme characteristics. Further systematic studies are needed to clarify these differences.

Domain Organization in Restriction Subunit

Multiple sequence alignment of all known and putative Res subunits suggests a modular structure (Figure 1(b)).

Figure 1 Modular structure of type III restriction enzyme. (a) Mod subunit showing the location of conserved amino acid sequence regions; catalytic motif, DPPY (motif IV) and AdoMet-binding motif, FXGXG (motif I). (b) Res subunit showing the location of conserved sequences, helicase motif, and putative endonuclease motif.

Table 1 Properties type III restriction enzymes

Enzyme	Source	Recognition sequence	Subunit composition	Cofactor requirement for restriction
EcoP15I	Plasmid P15B in <i>E. coli</i> 15T ⁻	5'-CAGCAG-3'	Res ₂ Mod ₂	Mg ²⁺ , ATP, AdoMet?
EcoP1I	Prophage P1	5'-AGACC-3'	Res ₂ Mod ₂	Mg ²⁺ , ATP, AdoMet?
StyLTI	<i>Salmonella typhimurium</i>	5'-CAGAG-3'	Res ₂ Mod ₂	Mg ²⁺ , ATP, AdoMet
HinfIII	<i>Haemophilus influenzae</i>	5'-CGAAT-3'	Res ₂ Mod ₂	Mg ²⁺ , ATP
PstII	<i>Providencia stuartii</i>	5'-CATCAG-3'	Res ₂ Mod ₂	Mg ²⁺ , ATP, GTP, CTP
LlaFI	<i>Lactococcus lactis</i>	ND	ND	Mg ²⁺ , ATP
BceSI	<i>Bacillus cereus</i>	ND	ND	Mg ²⁺ , ATP
PhaBI	<i>Pasteurella haemolytica</i>	ND	ND	ND
NgoAXP	<i>Neisseria gonorrhoeae</i>	5'-CCACC-3'	ND	ND

ND, not determined; A, site of methylation.

The C-terminus contains the PD(x)_n...(D/E)XK endonuclease motif that is commonly present in the catalytic center of restriction endonucleases. Sequence analysis of the Res subunit of EcoP1I and several putative Res subunits revealed the so-called DEAD box motif that is present in the helicase superfamily II. The members of the DEAD family of helicases have seven conserved motifs (motifs I, IA, and II–VI). The first motif of this family resembles the Walker A domain commonly present in ATPases. Mutational analysis of motif I resulted in a loss of DNA cleavage and ATP hydrolysis, while that of motif II significantly decreased ATP hydrolysis but had no effect on DNA cleavage. These motifs must, therefore, clearly play a role in ATP hydrolysis. Mutations in motif VI abolished both the DNA cleavage and ATPase activities, while mutations in putative endonuclease motif abolished DNA cleavage, but not ATP hydrolysis.

Domain Organization in Modification Subunit (DNA MTase)

The Mod subunit of type III restriction enzymes, EcoP1I, EcoP15I, HinfIII, and possibly other systems, alone can recognize and methylate the cognate sites. A unique feature of methylation by type III R–M systems is that only one strand of the asymmetric recognition sequence is methylated.

Sequence comparisons and biochemical studies in conjunction with site-directed mutagenesis have established the fact that the Mod subunit of the type III R–M systems contains the target recognition domain (TRD). TRD is a highly diverse and variable region in Mod subunit. So far, all the MTases belonging to this class of enzymes have been known to methylate adenine residues in their respective recognition sequences (Table 1).

Like all other N⁶-adenine MTases, the type III restriction enzymes contain two highly conserved sequences, FxGXG (motif I) and DPPY (motif IV), postulated to form the AdoMet-binding site and the catalytic site, respectively (Figure 1(a)). Extensive investigations on EcoP15I DNA MTase (M.EcoP15I) have revealed that this MTase adds a methyl group to the second adenine in the recognition sequence 5' CAGCAG 3' in the presence AdoMet and Mg²⁺. Mutations in motif I completely abrogated AdoMet binding but left the target DNA recognition unaltered. Mutations in motif IV resulted in the loss of enzyme activity but enhanced cross-linking of AdoMet and DNA, implying that DNA and AdoMet-binding sites are close to motif IV. Using chemical modification and site-directed mutagenesis, cysteine 344 and histidine 335 have been shown to play an essential role in the DNA methylation reaction catalyzed by M.EcoP15I. Both these amino acids are present in the putative TRD region. Curiously, M.EcoP15I possesses a PD(X)_n(D/E)XK like endonuclease motif (catalytic site of type II restriction endonucleases

that is shown to bind magnesium). However, the proline in this motif has been replaced by a methionine. M.EcoP15I requires magnesium ions for methylating DNA, and substitution of the acidic amino acid residues in the so-called 'endonuclease' motif abolishes magnesium binding and methylation activity. Intriguingly, substitution of methionine at position 357 by proline in the PDX_n(D/E)XK motif converted M.EcoP15I to a site-specific endonuclease. The cryptic endonuclease activity in EcoP15I DNA MTase perhaps provides an evolutionary link between restriction endonucleases and the MTase protein families.

M.EcoP15I binds about threefold more tightly to DNA containing its recognition sequence 5' CAGCAG 3' than to nonspecific sequences, in the presence of cofactors. In the presence of ATP, the discrimination between specific and nonspecific sequences increases significantly, suggesting a role for ATP in DNA recognition by these enzymes. M.EcoP15I makes contacts in the major groove of its substrate DNA. Both potassium permanganate footprinting and fluorescence spectroscopic measurements support a base-flipping mechanism for M.EcoP15I. EcoP1I DNA MTase (M.EcoP1I) methylates the second adenine in the recognition sequence 5' AGACC 3' in both single- and double-stranded DNA. The interesting property of binding and methylation of single-stranded DNA by M.EcoP1I might have an important role in the biology of single-stranded phages.

Mechanism of Action

Type III restriction enzymes show a strong preference for cleavage to occur when there are two copies of their asymmetric unmethylated recognition sites in an indirectly repeated, head-to-head orientation within a distance up to 3.5 kb. DNA cleavage occurs at one of the two sites, 25 or 26 nt downstream in the top strand and 27 or 28 nt downstream in the bottom strand. After cleavage, the enzyme remains bound to the still intact recognition site. DNA cleavage is blocked or reduced if (1) the sites are in the wrong orientation (tail to tail or head to tail), (2) there is only one site, or (3) a Lac-repressor molecule is bound to the DNA between the two head-to-head sites. Type III restriction enzymes must communicate between a pair of distant sites in order to cleave a DNA substrate. A specific protein-protein interaction is required, as two unrelated type III restriction enzymes cannot mutually activate cleavage of a linear DNA. It is proved that the type I enzymes extrude a DNA loop during translocation, and on the basis of the shared superfamily 2 helicase motifs a similar model has been suggested for the type III restriction enzymes.

The basis of long-distance communication for which a low-level ATP hydrolysis is required has not been accurately defined, and several models have been proposed, driven by either active DNA translocation or passive three-dimensional (3D) diffusion or invoking both DNA looping and limited translocation. A 'tracking-collision model' was first proposed to explain the DNA interaction and cleavage by type III restriction enzymes using R.EcoP15I as a model system (Figure 2(a)). This model states that one R.EcoP15I molecule bound to a recognition site produces a DNA loop of increasing size as it tracks along the DNA until it collides with another R.EcoP15I molecule bound to a second site tracking in the opposite

direction. ATP-hydrolysis-driven translocation thus positions two inversely oriented enzyme-site complexes for collision, which elicits conformational change of the enzyme molecules activating them for cleavage that occurs at a fixed distance away from one of the recognition sites. DNA loops originating from DNA translocation at two remote recognition sites within a DNA molecule were first observed by scanning force microscopy. To understand the mode of communication between distant recognition sites by type III restriction enzymes, atomic force microscopy (AFM) has been used to measure the DNA-protein interactions. These studies monitored the formation of translocated DNA loops in real time. The loop formation was both an ATP-dependent and -independent process. Based on the translocated DNA loops, a modified model was proposed in which R.EcoP15I initially employs diffusive looping to reduce the intersite DNA distance, followed by translocation-coupled extruded looping that brings the Res subunit into direct contact to cleave the DNA (Figure 2(a)). The low rates of ATP hydrolysis suggest that translocation-coupled looping cannot be the only mechanism, and that diffusive DNA looping must also act to reduce the lengths of DNA that the enzymes must translocate. The single-molecule resolution of fast-scan AFM further showed that the same R.EcoP15I-DNA complex is capable of both looping via extrusion coupled to translocation and diffusive looping. Thus, for two DNA-bound enzymes to communicate between two distal sites and trigger cleavage only when the sites are in a suitable orientation, enzyme dimerization, looping, and limited directional translocation driven by ATP hydrolysis are required. It thus appears that type III restriction enzymes have found the optimal strategy for their function by utilizing minimum energy for translocation prior to cleavage.

The DNA looping model based on AFM studies has been questioned. First, it was argued that it is not possible to conclude from the AFM studies that the events observed are necessary steps before DNA cleavage, because it does not measure both DNA communication and cleavage. Second, DNA attachment to a charged mica surface may have imposed a 2D geometry that can bias conformational flexibility. To monitor DNA looping in 3D environment, magnetic tweezers were used where both DNA cleavage and looping were measured simultaneously. These studies showed that type III restriction enzymes communicate between their sites in a 1D manner without loop formation. DNA cleavage rates were similar to those in bulk solutions and cleavage was not affected by magnetic force applied by magnetic tweezers. Based on these observations, an alternative DNA sliding mechanism was proposed in which restriction enzyme remains bound to DNA via weak electrostatic interactions (Figure 2(b)). Thermal activation then leads to a 1D random movement on DNA, in which both backward and forward steps occur with equal probability. The helicase domain produces a conformational switch from a DNA-recognition mode to a DNA sliding mode. The original binding orientation of enzyme to DNA is retained because enzyme is not released from DNA. If the enzyme eventually encounters a second enzyme molecule at another target site, cleavage of head-to-head DNA sites can occur. The model proposed for cleavage of linear DNA molecule explains that the enzyme moves in a direction and, upon encountering an end, dissociates from DNA, making cleavage less efficient.

Figure 2 Schematic diagram showing the models proposed for DNA cleavage by type III restriction enzymes. (a) Tracking-collision model; (b) DNA sliding mechanism; (c) one-dimensional diffusion of enzyme along the DNA.

When the DNA ends are capped by a bulky moiety, the sliding protein will be backtracked, making cleavage as efficient as on circular DNA. The model for cleavage of linear DNA describes a dynamic binding, sliding, and release scheme, where not every sliding event would lead to cleavage. On DNA with two directly repeated (head-to-tail) sites, the enzymes load onto the DNA in the same direction and, therefore, collisions between two enzyme molecules cannot produce DNA cleavage, since the favorable interactions to cleave DNA never occur. However, on DNA with sites in tail-to-tail repeat, the sliding model predicts that cleavage could occur if the first enzyme slides past the second site before the second enzyme binds. The observations that type III restriction enzymes can cut DNA even when the head-to-head target sites are adjacent can be explained by sliding mechanism.

Yet another model has been proposed to explain the mechanism of DNA cleavage by type III restriction enzymes in which the enzyme follows 1D diffusion along the DNA (**Figure 2(c)**). Studies with R.EcoP15I and linear DNA substrates demonstrated that enzyme can cleave linear DNA substrates containing a single recognition sequence. The diffusion occurs on the DNA unidirectionally first in the 5'–3' direction from the recognition site, and then switches the direction upon reaching the 3' end of DNA. Such a switching can be stalled by binding roadblock protein such as Lac repressor at the 3' end of a linear DNA molecule but not at 5' end. The change in translocation direction is possible with R.EcoP15I either by activating ATP hydrolysis of a Res subunit or by making a 180° rotation at the DNA ends. The absence of effect of different DNA termini

suggests activation of the second Res subunit for reverse translocation. In either case, the enzyme molecule at 3' DNA end would, therefore, resemble an enzyme molecule translocating from the opposite site, whose interaction with another molecule translocating toward the 3' side of a single site results in the formation of a collision complex.

Phase Variation and Type III R–M Systems

Phase variation is an adaptive process by which pathogenic bacteria undergo frequent and reversible phenotypic changes in expression of surface antigens such as lipopolysaccharide and outer-membrane proteins resulting from genetic alterations in specific loci of their genomes. This helps in colonization of the host, adaptation to host environments, and evasion of immune responses. Phase variation in many bacterial species is mediated by frequent and reversible changes in the lengths of short DNA sequence repeats associated with a subset of specific genes. The gain or loss of repeat units in these homo- or heteropolymeric tracts is thought to involve a mechanism of slipped-strand mispairing that can occur during chromosomal replication or in the course of a variety of DNA repair and recombination processes that require DNA synthesis. While phase variation is typically associated with genes encoding surface antigens, several host-adapted bacterial pathogens have MTases (*mod* gene) associated with type III R–M systems, which contain single tandem repeats that are prone to phase variation (*Pasteurella haemolytica*, *Haemophilus influenzae*, and

Helicobacter pylori) or are predicted to have phase variable genes (*Neisseria gonorrhoeae* and *Neisseria meningitidis*).

The number of repeats within the *mod* gene influences the rate of phase variation and expression of the *mod* gene. Due to mutations within the *res* gene, restriction enzyme is not functional. Therefore, the evolution of type III R–M system into epigenetic modulators for controlling gene expression results in loss of the DNA restriction function. In *H. influenzae*, the random switching of the *modA* gene controls expression of a phase variable regulon of genes (a ‘phasevarion’) via differential methylation of the genome in the *modA* ON and OFF states. This was the first report of the coordinated random switching of a regulon of genes, and considering the wide distribution of phase variable type III R–M systems this phenomenon may represent a widely used mechanism in bacterial pathogens. *H. pylori*, *N. gonorrhoeae*, and *N. meningitidis* contain multiple phase variable *mod* genes, whereas *H. influenzae* has only a single *mod* gene. The striking feature of two type III R–M genes (*ngoAXP* and *ngoAORF641P*) is the presence of tetra- and pentanucleotide repeats at the 5′ end of their *mod* genes. Some studies with these genes showed that the changes in the tetra- and pentanucleotide repeats in the 5′ end of *mod* gene results in phase variation and may also control expression of different *N. gonorrhoeae* genes. The phylogenetic studies of *mod* genes of pathogenic *Neisseria* strains indicated that differences in the DNA recognition domain within the *mod* gene resulted in distinct *mod* alleles. Based on differences in the DNA recognition domain, several different alleles were found (*modA11*, *modA12*, *modA13*, *modB1*, and *modB2*), and this suggested the existence of multiple phase variations within the pathogenic *Neisseria*, each regulating a different set of genes. Since each strain has both *modA* and *modB*, these genes switch independently and there are thus four potential combinations of *mod* gene expression.

The presence of phase-variable type III R–M systems has led to various predictions about their role in the biology of bacterial pathogens. The role of R–M systems is to protect bacterial cells against foreign DNA. The presence of phase-variable type III R–M systems may result in the provisional removal of the protection barrier by altering methylation patterns and might allow lateral DNA transfer within or between bacterial populations. For organisms with phase-variable R–M systems, the implications of *mod* switching with respect to restriction function are unclear. If a phase-variable *mod* gene associated with an active type III R–M system switches from OFF to ON after several rounds of bacterial replication, the result may be auto-restriction and death of the bacterium, as unmethylated targets in the bacterial chromosome would be vulnerable to cleavage. However, in many phase-variable R–M systems *Res* has been found to be inactive. The phase variable type III R–M systems may epigenetically regulate genes through differential methylation of genome. Furthermore, a phase-variable MTase could be involved in pathogenicity by randomizing virulence factor expression through global changes in methylation. The list of phase-variable R–M systems is expanding and it is proposed that the phase-variable expression of the type III R–M systems has evolved owing to the selective advantage conferred by the phase variation, which enables random switching of an organism between two distinct phenotypes.

Serial analysis of gene expression (SAGE) is a method for comprehensive analysis of the cellular gene expression patterns. The key feature in SAGE is the generation of a short sequence tag containing sufficient information to uniquely identify a messenger RNA (mRNA) transcript. Quantitation of the number of times a particular tag is observed provides the expression level of the corresponding transcript. The distance of 25–27 bp between the R.EcoP15I recognition and cleavage sites in the DNA molecule is the longest defined distance known so far for any restriction endonuclease. In addition, the characteristic property of R.EcoP15I to cleave optionally at only one of two interacting DNA sites, yielding heterogeneous digestion products, makes it an ideal tagging enzyme in the SuperSAGE method of transcriptome analysis.

The cleavage of fluorescence-labeled DNA substrates by R.EcoP15I has been successfully used in determining the number of CAG triplet repeats present in the Huntington’s disease (HD) gene (30–180 CAG repeats on chromosomes of HD patients as compared to 6–37 repeats on chromosomes of unaffected individuals).

It is generally thought that types I and III restriction enzymes do not perform multiple rounds of catalysis unlike the type II restriction enzymes. No turnover of the enzyme could be measured with respect to their cleavage function. Therefore, it is interesting to determine whether one is justified calling these proteins as enzymes. Phage DNA after endonuclease restriction is further degraded by bacterial exonucleases. Type III restriction enzymes recognize specific asymmetric sequences and cut DNA 25–27 bp away from the recognition site. After cleavage, the enzyme remains bound to the DNA. It has been quite clearly shown with R.EcoP15I that the intact recognition site (5′-CAGCAG-3′) on the cleaved DNA sequesters the restriction enzyme, thus decreasing the effective concentration of the enzyme. When the restriction assay was performed in the presence of exonucleases, the removal of cleaved DNA by exonucleases released R.EcoP15I to perform further rounds of catalysis. It is, therefore, tempting to postulate that type III restriction enzymes and, possibly, other enzymes, which cleave sufficiently away from their recognition sites, depend on exonucleases to perform multiple rounds of catalysis and to act as efficient endonucleases. The importance of functional cooperation between transacting proteins in the modulation of enzyme activity cannot be, therefore, underscored.

Glossary

Base pairs Bases associated by hydrogen bonds and hydrophobic forces.

Copy number variation (CNV) A segment of chromosomal DNA, usually 1 kb in length or more, which is present in varying number in the genome of different individuals.

DNA secondary structure A DNA conformation (non-B-DNA) different from the antiparallel right-handed double helix, B-DNA.

Slippage The annealing of an array of repeating DNA motifs on one strand of duplex DNA with the array on the complementary strand in an out-of-register manner.

Supercoiling The high-energy state generated by unwinding the helical duplex DNA when the two ends of the molecule are not free to rotate, as it occurs in the cell.

Translocation The process in which the end of a broken chromosome is joined with the end of another broken chromosome.

B-DNA

In 1980, the crystal structure of a helical turn of DNA was reported, which confirmed the model proposed by Watson and Crick in 1953. Since then, analyses of many sequences confirmed that the structure of DNA (B-DNA) is a right-handed double helix rotating about a central axis of symmetry and forming a major and a minor groove. The Watson and Crick base-pairing scheme between a purine and pyrimidine base (adenine (A) with thymine (T) and cytosine (C) with guanine (G)) was also confirmed. Deviations from these pairings (mismatches) perturb the helical structure of duplex DNA and can be corrected by cellular DNA repair mechanisms, including base excision repair (BER), nucleotide excision repair (NER), and mismatch repair (MMR).

Z-DNA

The first crystal structure of a DNA minihelix, reported in 1979, revealed a left-handed double helix formed by the self-complementary d(CG)₆ hexamer. It was called Z-DNA because of the zigzag shape of the phosphate and sugar backbone.

Chemistry

Z-DNA can form at alternating purine–pyrimidine (RY·RY) sequences (where R indicates a purine, A or G, and Y indicates a pyrimidine, C or T; the dot designates the complementary strands), such as the repeating (CG·CG)_n and (CA·TG)_n motifs (Figure 1). Structurally, the Z-DNA helix is more elongated than B-DNA; it lacks a major groove and the minor groove is very narrow and deep. The left-handedness is caused by the alternation of the N-glycosidic bonds between the *anti* and the *syn* conformations for the pyrimidines and purines, respectively. Both the B- and the Z-helices remain fully stacked since most of the helical distortion is dissipated over the two bases

flanking the Z-helix (B–Z junctions), which extrude into the solvent and become unpaired; these junctions are thought to be unstable and susceptible to oxidative damage, chemical modification, and cleavage *in vivo*. In the human genome, Z-DNA-forming tracts are often interrupted, for example, (CG·CG)₃A(CG·CG)₃. These interruptions disrupt the Z-DNA helix and create a Z–Z junction. Contrary to B–Z junctions, the bases forming a Z–Z junction are not extruded; however, they retain substantial conformational distortion that partially disrupts stacking within the overall Z-helix. Similar to other non-B-DNA structures, Z-DNA represents a high-energy state for DNA; *in vivo*, most energy required for the B to non-B transitions is thought to be supplied by negative supercoiling, a topological state of chromosomal DNA.

Biology

Estimates of ~300 000 alternating (RY·RY)_{≥6} motifs are present in the reference human genome sequence (see list of Relevant Websites), indicating that the potential sites for Z-DNA formation are higher than expected by chance alone. These sequences were probed with a peptide specific for Z-DNA for their existence in the left-handed conformation in the human A549 lung cancer cell line and ~7000 sites were found. Of these, 186 occurred at identical loci in multiple cells, suggesting that these sites may represent hot spots for Z-DNA formation *in vivo*. The most frequent hot-spot colocalization (46/186, 25%) occurred in centromeres, suggesting a putative role in kinetochore formation during mitosis or meiosis and the proper segregation of chromatids into daughter cells. Another 66 hot spots occurred within transcribed regions, mostly (49/66, 74%) in introns, supporting a role in gene transcription. No correlation was found between the presence of a Z-DNA hot spot and the level of gene transcription; thus, it remains to be determined whether Z-DNA activates or represses transcription on a genome-wide scale. Substantial evidence supports the conclusion that a Z-DNA tract is refractory to nucleosome assembly. Thus, Z-DNA formation at promoter or other regulatory sites is

Name	Conformation	General seq. requirements	Example of sequence

Cruciform		Inverted repeats	<u>TCGGT</u> _x <u>ACCGA</u> <u>AGCCA</u> _y <u>TGGCT</u>
Slipped (hairpin) structure		Direct repeats	<u>TCGGT</u> <u>TCGGT</u> <u>AGCCA</u> <u>AGCCA</u>

Figure 1 Common types of DNA secondary structures. The DNA strands and their folding are depicted as ribbons. For quadruplex DNA, the idealized folding of single-stranded DNA into an intramolecular quadruplex is shown, highlighting the *anti* and *syn* orientation of G residues connected by lateral (*L*), diagonal (*D*) or chain reversal (*CH*) loops. For triplex DNA, one of four possible isomers is drawn, that is, the 3'-RRY isomer, in which the 3' half of the purine-rich strand of the R-Y mirror repeat engages in Hoogsteen hydrogen bonding with the 5' half of the R-Y mirror repeat. The other three isomers correspond to 5'-RRY, 3'-YRY, and 5'-YRY. For Z-DNA, the single-stranded B-Z junctions are indicated. *x* and *y*, ~1–5 of any nt combination separating inverted or mirror repeats (loops). Adapted from Zhao J, et al. (2010) Non-B DNA structure-induced genetic instability and evolution. *Cellular and Molecular Life Sciences* 67: 43–62.

expected to play a role in transcription by exposing free DNA to regulatory factors. Proteins that have been found to bind specifically to Z-DNA share a common motif, named Z α . In addition to the human RNA-editing enzyme ADAR1, the Z α domain is also found in the DNA-dependent activator of interferon regulatory factor (DAI, also called DLM-1 and ZBP1), PKR-like eIF2 α kinase (PKZ), which is functionally related to the dsRNA-dependent protein kinase PKR, and E3L, a vaccinia virus immediate early protein. These proteins are related by their activity in binding cytosolic double-stranded RNA (dsRNA) and double-stranded DNA (dsDNA), most likely as a means to elude (E3L) or trigger a cascade of signaling events in response to viral infection. Thus, the formation of Z-DNA is thought to play a role in infection-related processes.

Triplex DNA

The association of nucleic acids into three-stranded structures (triplex DNA or H-DNA) was reported in 1957 with synthetic

polymers and confirmed in 1968 using naturally occurring sequences (Figure 1).

Chemistry

In three-stranded nucleic acids, consecutive purine bases in a B-DNA duplex engage a third strand through Hoogsteen hydrogen bonding in the major groove of the underlying duplex molecule (Figure 2).

The formation of a triplex structure requires DNA to contain mostly purines on one strand and thus mostly pyrimidines on the complementary strand (R-Y), and that a mirror repeat symmetry is created. In intramolecular triplexes, one-half of the mirror repeat (the purine-rich or pyrimidine-rich strand) dissociates from the complementary strand and folds back to engage the recipient purine-rich strand of the remaining mirror repeat in the major groove. Hence, this type of structure may take place during replication or transcription, at a time when the complementary strands are separated and negative supercoiling is generated. Alternatively,

Figure 2 Hydrogen bonding schemes in triplex DNA and G-tetrads: (a) base triplets in the RRY-type of triplex DNA and (b) base triplets in the YRY-type of triplex DNA. Different colors signify antiparallel strand orientations. For each base triplet, the Hoogsteen–hydrogen bonded base is shown on the left. (c) G-tetrad; typical arrangement of G residues associated through Hoogsteen hydrogen bonds. Strand orientation and *syn/anti* conformations are not specified.

in an intermolecular triplex, an exogenous oligonucleotide (triplex-forming oligonucleotide or TFO) is added to the cell to bind a specific chromosomal (R-Y) duplex target sequence, also through Hoogsteen hydrogen bonding in the major groove. The use of TFOs is currently being explored as a therapeutic means to inhibit gene expression (oncogenes) in cancer or to directly inactivate genes by delivering a DNA damaging agent via the TFO. For any given intramolecular triplex, four isomers are possible: two in which the 3' half of the mirror repeat engages in Hoogsteen hydrogen bonding and two in which the 5' half of the mirror repeat engages in Hoogsteen hydrogen bonding. For each of these cases, either the pyrimidine-rich sequence engages as the third strand in a parallel orientation with respect to the recipient purine-rich strand or the purine-rich sequence engages as the third strand in an antiparallel orientation with respect to the recipient purine-rich strand.

Biology

Approximately 625 000 R-Y tracts with a mirror repeat symmetry formed by at least 10 bases are present in the reference human genome, a number of which (814) are embedded in very long R-Y tracts exceeding 250 nucleotides (nt) in length. These long tracts are enriched in both the PAR1 region, a segment of ~2.5 million DNA bases common to both the X- and Y-chromosomes and indispensable for meiotic recombination and chromosomal segregation and in genes expressed in the brain that function in the transmission of the nerve impulse at synapses. A large fraction of the genome is believed to undergo transcription on both strands of the DNA (sense and antisense transcription). Regions with long R-Y tracts tend to associate with poor antisense transcription and also with weaker sense transcription than genome-wide average, suggesting a genome-wide role for triplex DNA in gene function/regulation. In addition, endogenous

H-DNA-forming sequences that map to translocation break-points have been found to induce DNA double-strand breaks, leading to genomic instability. Such findings implicate these structure-forming sequences in cancer etiology.

Quadruplex DNA

The ability of G residues to assemble in tetrameric arrangements (tetraplex DNA, four-stranded DNA, or G4-DNA) was noted in 1962. In 1988, tetraplex DNA was reported in biological systems.

Chemistry

Quadruplex DNA can form at DNA sequences composed of four repeating motifs, each containing at least two G residues and separated by ~1–7 bases (spacers). The basic unit of quadruplex DNA is a G-tetrad, a planar array of four Gs, one from each of the four repeating motifs, stabilized by Hoogsteen hydrogen bonding and monovalent ($K^+ > Na^+$) cation coordination (Figures 1 and 2). G-tetrads stack on one another and are connected by the bases in the spacers, which form loops. The human telomeric sequence $(TTAGGG)_n$ has served as a prototype for structural characterization studies on quadruplex DNA. Various conformations have been reported, depending on buffer conditions and sequence lengths, in which the G-tetrad carrying strands may run either parallel or antiparallel, the Gs may adopt either the *syn* or *anti* conformations, and the loops provide connectivity in lateral, diagonal, or chain-reversal fashions.

Biology

The number of sites in the reference human genome containing predicted quadruplex-forming sequences exceeds 374 000.

As mentioned, chromosomes end with long stretches of $(TTAGGG)_n$ repeats, the last 100–200 of which are in the single-stranded form. In addition, several bioinformatic analyses have demonstrated a significant enrichment of quadruplex-forming motifs near (± 500 nt) transcription start sites and to transcription termination sites in numerous genes. Genome-wide probing of quadruplex DNA with a quadruplex-specific single-chain antibody further demonstrated that binding of the antibody to the expected DNA secondary structures caused

either an increase or a decrease in transcriptional activity in 1767 genes, supporting the conclusion that formation of quadruplex DNA plays a physiological role in gene expression regulation by (1) either inducing or repressing transcription, depending on the specific gene (Figure 3) and (2) favoring transcriptional termination. At the messenger RNA (mRNA) level, the localization of quadruplex DNA in 5-untranslated (5-UTR) regions has also been reported to elicit an inhibitory effect on translation.

Figure 3 Quadruplex DNA and the regulation of *c-MYC* gene expression. (a) The promoter region of the *c-MYC* proto-oncogene includes four main promoters (P0-P3): two of which (P1 and P2) lie close to the main transcription start site, five nuclease hypersensitive elements (NHE), one of which (NHE III₁) contains a quadruplex-forming sequence (TGGGGAGGGTGGGGAGGGTGGGGAAGGTGGGGA), and a far upstream element (FUSE), which senses the torsional stress (negative supercoiling) accumulated in the DNA double-helix during the process of transcription. FBP (FUSE-binding protein) binds to single-stranded FUSE to activate and maintain *c-MYC* transcription. Alternatively, FIR (FBP-interacting repressor) binds FBP returning FUSE to double-stranded DNA and *c-MYC* transcription to basal levels. A number of binding sites for other transcriptional regulators are present in the promoter region. (b) Binding of Sp1 to double-stranded DNA within the NHEIII₁ region turns-on transcription. (c) Duplex DNA in the NHEIII₁ region is in equilibrium with single-stranded DNA; each strand binds a specific transcriptional activator (CNBP recognizes the G-rich strand whereas hnRNP K binds the complementary C-rich strand), yielding a complex that supports active transcription. (d) The single-stranded NHEIII₁ region folds into (a) quadruplex structure(s) on the G-rich strand and an i-motif on the C-rich strand, which prevents transcriptional activator binding and thus represses transcription. Stabilization of quadruplex DNA by intercalators, such as TMPyP4, stably represses transcription. Reprinted from Gonzalez V and Hurley LH (2010) The *c-MYC* NHE III₁: function and regulation. *Annual Review of Pharmacology and Toxicology* 50: 111–129.

Telomeres, that is, the protein-DNA complexes at the chromosomal ends, have also been probed for quadruplex formation. One of the proposed biological roles for quadruplex DNA at telomeres is related to the formation of T-loops, DNA loops where the extreme (2–3 repeats) 3′ single-stranded TTAGGG repeats fold back into duplex DNA with the assistance of proteins (such as TRF2) and engage with similar TTAGGG repeats to form quadruplex structures. The putative function of T-loops would be to provide protection for linear chromosomal ends against degradation.

Pharmacology

In the process of developing TFOs as tools for targeting specific genes, it was discovered that some G-rich oligonucleotides (GROs) could inhibit cancer cell viability without targeting the intended gene(s). Further research led to the finding that GROs assemble into stable secondary structures, including quadruplex DNA, before entering the cell, and that this folding induces their binding to nucleolin at the cell surface. The nucleolin–GRO complexes were then shown to migrate into the cell, leading to cell-cycle arrest, inactivation of the nuclear factor kappa B (NF- κ B) pathway, the induction of tumor suppressors, and induction of cell death, which ultimately resulted in an anti-proliferative effect for cancer cells. Nucleolin is present within the cell normally, but actively translocates to the plasma membrane in many cancer cell types. Thus, GRO activity appears to be selectively targeting certain cancer cells. The use of AS1411, a 26-mer GRO, is currently in phase II clinical trials to treat acute myeloid leukemia (AML) and renal cell carcinoma.

Cruciforms and Slipped Structures

Cruciforms and slipped structures are formed by inverted and direct repeats, respectively, under the influence of negative supercoiling. Contrary to the conformations described above, cruciforms and slipped structures do not require specific base composition.

Chemistry

In inverted repeats, a DNA sequence is followed by its complementary sequence, usually separated by a loop, on the same strand of DNA. Thus, each complementary strand may fold onto itself rather than binding to its complement, thus forming two fully paired intramolecular Watson–Crick duplexes, each with a single-stranded loop, that is, a cruciform structure (Figure 1). Fluorescence resonance energy transfer (FRET) studies indicate that in the presence of magnesium ions, a key cellular metal, cruciforms adopt an x-shape structure with pairwise antiparallel coaxial stacking of the neighboring helices. Two different conformations exist in equilibrium in solution, in which helices exchange partners on timescales of ~ 100 ms. Interestingly, no parallel stacked conformations have been detected at time resolutions of 1 ms; hence, cruciform arms extruding from chromosomal DNA are expected to lie in close proximity to the continuous and adjacent double helix. By contrast, tandem repeats may give rise to

bases looping out from duplex DNA (slipped DNA) when out-of-register re-annealing, such as during transcription, occurs.

Biology

Approximately 200 000 short (>10 bases) inverted repeat sequences separated by small loops are present in the reference human genome sequence. In addition, 96 large inverted repeats (arm size >8 kb with $>95\%$ sequence similarity), including nine inverted repeats with arm length exceeding 100 kb and displaying near identical ($>97\%$) sequence composition, have been identified. Five of these are present on the male-specific region of the Y-chromosome (MSY) and contain gene/gene classes that display testis-restricted expression with a function in sperm production and maturation. The palindromic architecture of the MSY gene families (amplicons) has been recognized as a critical feature for the genetic stability and gene function associated with the Y-chromosome. Indeed, the symmetric position of genes along the palindromic arms is believed to facilitate gene conversion events, which have been shown to occur frequently at these locations. For the Y chromosome, such high rates of gene conversion are believed to represent an efficient means for counteracting the threat of gene decay, which would otherwise be expected in the absence of recombination with a homologous chromosome. Gene conversion events may take place in various ways, including the formation of large cruciform structures.

Simple tandem repeat sequences are also common in the human genome reference sequence and display high rates of length variation among individuals, a feature attributed in part to the propensity of the repeat units to slip relative to one another during transcription and replication. Particularly important from physiological and pathological standpoints is the genome-wide distribution of trinucleotide repeats in exons, since their length polymorphisms in the general population also encode polymorphic homo-amino acid runs in the translated protein products, potentially altering their function. Several bioinformatic analyses concur with the conclusion that coding trinucleotide repeats are significantly overrepresented in specific classes of genes, such as those encoding transcription factors and proteins involved in transcription and its regulatory circuitries. The current view is that homo-amino acid runs contribute to protein intrinsic disorder, that is, unstructured domains in monomeric proteins that are critical for function. Indeed, intrinsically disordered protein domains are recognized as playing important roles in protein–protein and protein–nucleic acids interactions, whereby their flexibility to adopt various conformations enable high-affinity interactions upon binding with structurally diverse partners. Therefore, the ability of trinucleotide repeats to expand and contract within relatively short evolutionary times is believed to have been exploited as a means to explore and/or fine-tune a number of diverse protein–protein and protein–nucleic acids interactions during the course of evolutionary time.

Pathology

More than 30 human genetic disorders, mostly affecting the central nervous system and neuromuscular functions, have

been associated with the expansion of trinucleotide repeats and other microsatellites, in coding exons, untranslated regions, and introns of genes. In general, up to ~35–50 repeat units are present at any individual locus in normal alleles; however, large expansions of up to thousands of repeat units have been observed in affected individuals. Most of the expansion process is thought to take place early during embryonic development and/or gametogenesis, with further repeat instability continuing later during the lifetime of somatic tissues. Although the precise mechanisms leading to trinucleotide expansion remain a subject of intense investigation, the formation of aberrant DNA structures (including hairpins, stem-loops, and other intermediate structures) during replication and/or transcription is believed to play pivotal roles.

In addition to trinucleotide repeats, evidence is accumulating to suggest that other DNA repetitive elements are also involved in inducing genomic instability leading to human disease. Indeed, extensive work has been conducted on the characterization and the physical properties of DNA sequences involved in specific chromosomal translocations, such as the recurrent t(11;22) associated with the Emanuel syndrome (Figure 4). This composite work strongly suggests that large (~300–500 nt) cruciform structures may form on chromosomes 11 and 22, which are then cleaved and joined between the two chromosomes, resulting in a translocation.

A number of bioinformatic analyses aimed at analyzing the types of DNA sequences found at sites of pathological gene conversion events, gross chromosomal rearrangements and copy number variation (CNV), support the conclusion that repetitive motifs are found more often than expected by chance. These analyses indicate that DNA secondary structures, rather than the primary DNA sequences *per se*, facilitate DNA transactions leading to changes in genomic architecture that

result in disease. Analogous genomic changes, such as those associated with CNV, are also likely to contribute to phenotypic differences among individuals.

Molecular Biology

A number of studies conducted on trinucleotide repeats (such as CTG·CAG) *in vitro* and *in vivo* support the notion that the MMR proteins Msh2 and Msh3, components of the MutS β complex, are required for the expansion processes leading to their pathological expansion. Looped-out structures engineered *in vitro*, which are thought to simulate the conformations formed by the repeats *in vivo*, are indeed recognized and cleaved by MMR proteins. Additional steps involved in the expansion process appear to include interactions of the repeats (or most likely their underlying secondary structures) with incoming replication forks.

Other DNA secondary structures, such as triplexes, quadruplexes, and 4-way junctions (cruciform-like), have been shown *in vitro* to serve as specific targets for a number of DNA and RNA helicases, which resolve their folded conformations using nucleoside triphosphate (NTP) hydrolysis. Among these, WRN, BLM, and RECQL4 belong to the evolutionarily conserved family of recQ-helicases, and inactivating mutations in any of the corresponding genes cause the Werner, Bloom's, or Rothmund-Thomson syndromes, respectively, conditions characterized by widespread genetic instability and predisposition to cancer. These results prompt speculation that the maintenance of genome integrity is in part elicited by numerous helicase activities on DNA secondary structures, whose resolution alleviates their potential interference with key cellular transactions, such as DNA replication and transcription.

Figure 4 Cruciform DNA and the Emanuel syndrome. The human t(11;22) translocation is the most commonly recurrent non-Robertsonian translocation. In most patients, the breakpoints on chromosomes 11 and 22 cluster at the center of palindromic A/T-rich DNA (PATRR) regions, which comprise long (~350–500 nt) A/T-rich sequences with inverted repeat symmetry. The PATRR11 and PATRR22 do not share sequences homology; however, they are thought to extrude large cruciform structures (insets) that are then cleaved at their center loops (the breakpoint cluster region) and joined aberrantly, yielding the der(11) and der(22) chromosomes. The Emanuel syndrome is caused by the inheritance of a supernumerary der(22) chromosome in the offspring. Reprinted from Bacolla A, et al. (2010) Non-B DNA structure and mutations causing human genetic disease. *Encyclopedia of Life Sciences*.
